TEQ

Indicates that the ion abundance ratio for this analyte did not meet the control limit. The reported value represents an estimated concentration.

Lower Quantification Limit, based on the lowest calibration level corrected for sample size, splits and dilutions.

Estimated Maximum Possible Concentration – elevated detection limit due to interference or positive id criterion failure

Indicates that the analyte was positively identifed. The associated numerical result is an estimate.

Indicates the Toxic Equivalency

TEF

LQL M

U

EMPC

Indicates the Toxic Equivalency Factor

Indicates that a peak has been manually integrated.

Indicates that this compound was not detected above the EDL.

TEF Indicates the Toxic Equivalency Factor TEQ Indicates the Toxic Equivalency

Lower Quantification Limit, based on the lowest calibration level corrected for sample size, splits and dilutions.

Estimated Maximum Possible Concentration – elevated detection limit due to interference or positive id criterion failure

Indicates that the ion abundance ratio for this analyte did not meet the control limit. The reported value represents an estimated concentration.

Indicates that the analyte was positively identifed. The associated numerical result is an estimate.

Indicates that a peak has been manually integrated.

Indicates that this compound was not detected above the EDL.

Notes/Abbreviations
"." = "-2" (reported less than the detection limit).
Highlighted cells indicate a blank adjustment was made (see Appendix C).
" = used in report tables
NA = not applicable; PCB TEQ calculated.

# **ATTACHMENT 3**

# **Data Validation**

### **Attachment 3: Data Validation**

ToxStrategies performed data validation to assess "data quality and usability" in general accordance with USEPA's National Functional Guidelines (USEPA, 2017), as well as the use of professional judgment. All of the data were considered acceptable, with the following exceptions noted in the data review comments for ALS Workorders L2526958 and L2526958. Data review comments organized by ALS Workorder are provided below.

#### ALS Workorder: 2031166

Hexavalent chromium was not detected in the laboratory method blank; the laboratory control sample / laboratory control sample duplicate (LCS/LCSD) percent recoveries and relative percent difference (RPD) were within quality control (QC) limits.

#### ALS Workorder: 2031169

Hexavalent chromium was not detected in the laboratory method blank; the LCS/LCSD percent recoveries and RPD were within OC limits.

#### ALS Workorder: 2031177

No metals were detected in the laboratory method blanks; the LCS/LCSD percent recoveries and RPDs were within QC limits.

#### ALS Workorder: 2031255

Arsenic and lead were not detected in the laboratory method blanks; the LCS/LCSD percent recoveries and RPDs were within QC limits.

#### ALS Workorder: 2031257

Arsenic and lead were not detected in the laboratory method blanks; the LCS/LCSD percent recoveries and RPDs were within QC limits.

#### ALS Workorder: 2031258

Pentachlorophenol was not detected in the laboratory method blank; the LCS/LCSD percent recoveries and RPD were within QC limits.

#### ALS Workorder: 2031261

Benzene, ethylbenzene, naphthalene, and styrene were not detected in the laboratory method blank; the LCS/LCSD percent recoveries and RPDs were within QC limits.

#### ALS Workorder: 2031263

Benzene, ethylbenzene, and naphthalene were not detected in the laboratory method blank; the LCS/LCSD percent recoveries and RPDs were within QC limits.

#### ALS Workorder: 2031264

The LCS/LCSD percent recoveries and RPD were within QC limits for respirable dust.

#### ALS Workorder: 2031269

Tetrachloroethylene was not detected in the laboratory method blank; the LCS/LCSD percent recoveries and RPD were within QC limits.

## ALS Workorder: 2031269

Organic and elemental carbon were not detected in the laboratory method blanks; the LCS/LCSD percent recoveries and RPD for organic carbon were within QC limits.

For the above-listed workorders, chemicals were not measured in the field blanks above the detection limit.

#### ALS Workorder: L2526958

The analytical method (Method 1668C) developed by USEPA (2010) provides guidance for evaluating the quality assurance/quality control results for the PCB analysis. Method 1668C indicates that "interferences and laboratory background levels"—not laboratory instruments—cause sample detections that are not otherwise observed in other chemical analyses (USEPA, 2010). As a result, the process for setting acceptable blank sample measurements is different from that for other analyses. For PCBs, the blank acceptance limit is calculated using the congener-specific minimum levels of quantitation (MLs; units of picograms [pg] per microliter [ $\mu$ L]) found in Table 2 of USEPA's Method 1668C (2010). Therefore, the congener-specific MLs represent the level at which the instrument can identify and quantify sample-specific analytes "based on the levels of contamination normally found in laboratories" (USEPA, 2010).

For each congener, the ML was calculated by multiplying the congener-specific ML (for an extract matrix in pg/ $\mu$ L) by 25  $\mu$ L (final analysis volume), by a factor of 2 (as stated in the method), and by a second factor of 2 (because the samples were split for two analyses: PCBs and dioxins/furans). For example, the extract matrix for PCB-001 is 1 pg/ $\mu$ L. Using the formula, the ML for the analysis was:

$$\begin{aligned} ML_{analysis}(pg) &= ML_{extract}(pg/\mu L) \times 25 \ (\mu L) \times 2 \times 2 \\ &= 1 \frac{pg}{\mu L} \times 25 \mu L \times 2 \times 2 \\ &= 100 \ pg \end{aligned}$$

The two field blanks (Sample IDs BA-3-BLANK and DFP-BLANK) and the two laboratory method blanks (swab and reagent matrix) were compared to their congener-specific MLs. Any detections below the ML are considered potentially to be related to laboratory contamination and not relevant to the sample itself.

All of the PCB congeners detected in the two laboratory method blanks and two field blanks were below their respective congener-specific ML, with the exception of PCB-209 measured at 270 pg in the swab blank matrix, which exceeded the congener-specific ML of 250 pg. Table 1 presents the field and method blank results for PCB-209.

Table 1. Field and method blank results for PCB-209

| Sample ID     | Sample Result (pg) | Congener-specific ML (pg) |  |  |  |
|---------------|--------------------|---------------------------|--|--|--|
|               | Field blanks       |                           |  |  |  |
| BA-3-BLANK    | 134                | 250                       |  |  |  |
| DFP-BLANK     | 59.5               | 250                       |  |  |  |
| Method blanks |                    |                           |  |  |  |
| Swab blank    | 270*               | 250                       |  |  |  |
| Reagent blank | 112                | 250                       |  |  |  |

<sup>\*</sup>The swab blank sample result for PCB-209 exceeded the congener-specific ML of 250 pg.

The extraction percent recoveries for the PCB congeners were evaluated for each sample, and all were within limits, with the exception of the extraction standard for PCB-209 in sample ENG-159-DFP-1 (0% recovery). Therefore, PCB-209 in sample ENG-159-DFP-1 was qualified as unusable.

The extraction percent recoveries of the PCB congeners for the laboratory control sample (LCS) were all within limits, with the exception of PCB-209. As indicated by the laboratory, the method blank detection of PCB-209 above the ML caused the extraction percent recovery (30%) to be below the acceptable limits (40%–145%). Professional judgment was used, and no additional data qualification was considered necessary.

A summary of the PCB-209 results for each sample and their resulting data review qualification are presented in Table 2.

Table 2. Summary of the sample results for PCB-209 and resulting data review qualification

| Sample ID      | Sample Result (pg) | Congener-specific<br>ML (pg) | Qualification based on ML |
|----------------|--------------------|------------------------------|---------------------------|
| BA-1           | 38.8               | 250                          | No qualification required |
| BA-2           | 222                | 250                          | No qualification required |

## **Blank Adjustments for PCB Data**

If a PCB congener was detected in a blank sample (field blank [sample IDs BA-3-BLANK, DFP-BLANK] and/or laboratory blank [swab and reagent matrix]), the maximum blank result was compared to the result for field samples. If the field sample was non-detect, no change was made. If the field sample was detected at a concentration less than two times the maximum blank sample result, the field sample result was considered a non-detect at the value reported. If the field sample was detected at a concentration more than two times the maximum blank sample, no change was made. Data that were qualified are noted in the Attachment 2-A calculations. Table 3 lists the maximum blank concentrations for each congener.

Table 3. Maximum concentration detected in a blank sample

| Congener Concentration (pg) |
|-----------------------------|
|                             |
| 2.6                         |

| 270                         |
|                             |

#### ALS Workorder: L2526958

In general, chlorinated dioxins/furans were not detected in the two field blanks (sample IDs BA-3-BLANK and DFP-BLANK) or in the laboratory method blanks (swab and reagent matrix), with the following exceptions:

- OCDD was detected at 6.88 pg in the swab blank, slightly above the detection limit of 5.5 pg
- OCDD was detected at 4.48 pg in the reagent blank, slightly above the detection limit of 3.0 pg
- 1,2,3,6,7,8-HxCDF was detected at 0.870 pg in the swab blank, slightly above the detection limit of 0.83 pg
- 1,2,3,4,6,7,8-HpCDF was detected at 1.43 pg in the reagent blank, slightly above the detection limit of 1.1 pg
- OCDF was detected at 8.88 pg in the swab blank slightly, above the detection limit of 6.5 pg.

In general accordance with USEPA's National Functional Guidelines (USEPA, 2017), no qualification is required if there is a detection in the method blank when the sample result is non-detect. Therefore, all sample results that were non-detect were not qualified.

When the sample result exceeded the maximum detected method blank result, the sample result was not qualified, based on professional judgement. The detections found in the method blanks were not considered likely to affect the detected sample results. In most cases, the minimum detected concentration was almost twice the blank detection; only the minimum concentration of OCDF was comparable to the blank concentration. Also, chlorinated dioxins/furans were not detected in the two field blanks (Sample IDs BA-3-BLANK and DFP-BLANK), suggesting that OCDF in blanks was not interfering with field sample analysis. Thus, none of the analytes detected above the detections in the blank samples were qualified.

Only sample ID 356-5 had a detection of OCDD (6.53 pg) that was less than the maximum detected blank result (6.88 pg). For this sample, ToxStrategies qualified the result with a "U" qualifier, and the sample result was revised to <6.53 pg, in general accordance with USEPA (2017).

A summary of the resulting sample qualifications, based on the laboratory method blank detections, is presented in Table 4.

Table 4. Summary of the sample results for selected dioxin/furan congeners and resulting data review qualification

| Sample ID          | Congener            | Sample<br>Result (pg) | Maximum<br>Detected Blank<br>Result (pg) | Qualification                                                        |
|--------------------|---------------------|-----------------------|------------------------------------------|----------------------------------------------------------------------|
| BA-1               | OCDD                | 35.6                  | 6.88                                     | Professional judgment was used and no qualification was required     |

| ENG-558-DFP-<br>01 | OCDF                | 14.1                  | 8.88                                     | Professional judgment was used and no qualification was required |

The extraction percent recoveries for the dioxins/furan sample results were within limits, with the exception of the following:

- The extraction standard's percent recovery of 28% was less than the minimum control limit of 32% in sample BA-2
- The extraction standard's percent recovery of 19% was less than the minimum control limit of 26% in sample BA-2

Because the concentration data in the samples are recovery corrected based on the extraction standard result, no additional action was required.

The extraction percent recoveries of the dioxin/furan congeners for the laboratory control sample (LCS) were all within limits.

The quality control (QC) sample reports are found in Attachment D-3-1, with the exception of those for PCBs and chlorinated dioxins/furans, for which the QC report is embedded in the laboratory report (see Attachment 1).

#### **Symbols and Definitions**

- \* Analyte above reporting limit or outside of control limits
- ▲- Sample result is greater than 4 times the spike added
- Sample and Matrix Duplicate less than 5 times the reporting limit
- Result is above the calibration range
- # The Matrix Spike, Matrix Spike duplicate or Matrix Duplicate is reported for your information only. The sample matrix may be inappropriate for the method selected.

RPD - Relative % Difference (Spike / Spike Duplicate)

ND - Not Detected (U - Qualifier also flags analyte as not detected)

NA - Not Applicable

#### **Symbols and Definitions**

\* - Analyte above reporting limit or outside of control limits

▲- Sample result is greater than 4 times the spike added

Sample and Matrix Duplicate less than 5 times the reporting limit

- Result is above the calibration range

# - The Matrix Spike, Matrix Spike duplicate or Matrix Duplicate is reported for your information only. The sample matrix may be inappropriate for the method selected. RPD - Relative % Difference (Spike / Spike Duplicate)

ND - Not Detected (U - Qualifier also flags analyte as not detected)

NA - Not Applicable

#### QC Report Authorization (/S/ is an electronic signature that complies with 21 CFR Part 11)

| Analyst          | Peer Review           |
|------------------|-----------------------|
| /S/ David Teynor | /S/ Thomas J. Masoian |
| 11/17/2020 15:05 | 11/17/2020 16:20      |

#### **Symbols and Definitions**

# - Analyte above reporting limit or outside of control limits

▲- Sample result is greater than 4 times the spike added

Sample and Matrix Duplicate less than 5 times the reporting limit

- Result is above the calibration range

# - The Matrix Spike, Matrix Spike duplicate or Matrix Duplicate is reported for your information only. The sample matrix may be inappropriate for the method selected. RPD - Relative % Difference (Spike / Spike Duplicate)

ND - Not Detected (U - Qualifier also flags analyte as not detected)

NA - Not Applicable

QC results are not adjusted for moisture correction, where applicable

#### 1 Introduction

ToxStrategies was contracted by the California Department of Industrial Relations (DIR), Commission on Health and Safety and Workers' Compensation (CHSWC), to conduct the study described herein, as outlined in California Assembly Bill (AB) 1400. AB 1400 was created to define fire mechanics' risk from exposures to carcinogens in the course of their employment as fire mechanics.

The study components include:

- Site visits to representative facilities in Los Angeles County, California
- Interviews and surveys with current and former fire mechanics to assess potential exposures to carcinogens
- Feasibility study to assess the data available to calculate cancer incidence among fire mechanics
- Occupational exposure measurements of carcinogens identified as potentially present in the workplace, to evaluate potential exposure to carcinogens
- Quantitative health risk assessment of potential increased cancer risk associated with exposure to carcinogens in the workplace.

ToxStrategies' approach to address these study components includes six tasks (provided in our proposal submitted to the DIR [ToxStrategies, Inc., 2020a]):

- Task 1: Structured literature review submitted; ToxStrategies, Inc., 2020b
- Task 2: Qualitative exposure assessment submitted; ToxStrategies, Inc., 2020c
- Task 3: Epidemiologic assessment feasibility study of cohort enumeration for future epidemiologic study design on-going
- Task 4: Quantitative exposure assessment submitted; ToxStrategies, Inc. 2020d
- Task 5: Cancer risk assessment calculation of theoretical excess cancer risks from occupational exposure to carcinogens; provided herein
- Task 6: Technical assistance to the DIR.

The purpose of Task 5, Cancer Risk Assessment, was to use the quantitative results from Task 4 to calculate the theoretical excess cancer risk from exposure to carcinogenic materials for workers with similar work activities (identified as similar exposure groups [SEGs]) and primary job tasks (as determined from the qualitative assessment in Task 2), using toxicity criteria relevant to California risk assessments. A summary of the five fire mechanic SEGs and their respective job tasks are provided in Table 1 (attached).

The cancer risk assessment is an estimate of the theoretical increased risk of developing cancer as a result of exposure to chemicals present in the workplace. This approach involves varying degrees of conservatism and ensures that cancer risk is not underestimated, which makes it probable that the estimated risk will be overestimated. It is important to consider that these risks are theoretical because they are not measured directly among fire mechanics, which could only be done through use of an epidemiology study (as discussed further in Task 3). The objectives, methods, results, and conclusions of Task 5 are provided herein.

#### 1.1 Objectives

The objectives of this cancer risk assessment were as follows:

- 1. Provide a qualitative summary of work practices and quantitative exposure assumptions used to define each of the relevant SEGs and exposures related to primary job tasks.
- 2. Estimate the theoretical probability of an increased risk of cancer as a result of exposure for each SEG and job task.
- 3. Discuss qualitatively potential exposures and risks for SEGs and job tasks for which sufficient quantitative information was not available to calculate risks.
- 4. Discuss areas of uncertainty affecting the quantification of risks.

#### 1.2 Scope

This risk assessment was prepared using the guidance of California health and regulatory agencies. In cases where such guidance was not available or not applicable, other sources of information, such as the United States Environmental Protection Agency (USEPA), the Occupational Safety and Health Administration (OSHA), and the National Institute of Occupational Safety and Health (NIOSH) were used. Site-specific information was used to develop the exposure assumptions used in the risk assessment calculations.

Quantitative risk assessments consist of four parts (National Research Council, 1983):

- Hazard Identification Identify the hazardous chemicals that are present and may result in exposure.
- Exposure Assessment Develop an understanding of the applicable exposure pathways, which include the exposure media, exposure points, exposure routes, and receptors. This also includes developing quantitative estimates for various exposure assumptions and exposure-point concentrations.
- Toxicity Assessment Review regulatory references to identify quantitative criteria that relate exposure to potential health risk.
- Risk Characterization Integrate the exposure and toxicity assessments to develop quantitative estimates of potential health risks. Risk characterization

also includes discussion of qualitative evaluations where quantitative evaluations were not possible, and assessing uncertainty in the underlying assumptions.

#### 2 Hazard Identification/Data Evaluation

ToxStrategies collected personal breathing zone (PBZ) air samples and surface wipe samples on November 3 and 4, 2020, at Air Operations (Pacoima), the Breathing Apparatus Shop (Pacoima), and the Eastern Fire Shop (Los Angeles). The selection of the chemicals of potential concern (COPCs), analytical sampling methods, and quantitative results of this exposure assessment are provided in the Task 4 report (ToxStrategies, Inc., 2020d). A summary of the results is provided below.

Chemicals related to two SEGs—(1) helicopter maintenance inspector painting/priming/sanding aircraft parts at Air Operations, and (2) the field-assigned fire equipment mechanic repairing fire apparatus or other equipment at a wildfire base camp—were not measured, because these activities did not occur during the period when sampling occurred. These potential exposures have been evaluated qualitatively (Section 5.2).

Additionally, six chemicals were not measured, because, although they have been identified as potential carcinogens, regulatory toxicity criteria were not available. Diethanolamine and tetrahydrofuran are present in chemicals used for helicopter maintenance at Air Operations. Cumene, tetrabromobisphenol-A, methyl isobutyl ketone, and diethanolamine are present in chemicals used by fire equipment mechanics at the Eastern Fire Shop. These chemicals are also addressed in the qualitative assessment (Section 5.2).

For chlorinated dioxins/furans and polychlorinated biphenyls (PCBs), 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) toxic equivalence (TEQ) values were calculated for reporting purposes. TEQs are calculated as the product of the congener-specific toxic equivalency factor (TEF) and the measured concentration for each relevant congener. Congener results in each sample that were non-detects were assigned values equal to 50% of the reporting limit for calculating the dioxin/furan/PCB TEQs. The concentrations of PCB congeners that do not have a TEF were summed for each sample (including 50% of non-detect values) for evaluation separately. The laboratory reports and calculations of the TEQ and non-TEQ totals are presented in the Task 4 quantitative exposure assessment (ToxStrategies, Inc., 2020d). Results in this section are presented only as TEQs or the sum for PCBs without TEFs.

#### 2.1 Air Sampling

PBZ air samples were collected for workers at Air Operations, the Breathing Apparatus Repair Shop, and the Eastern Fire Shop, to characterize their potential inhalation exposures during a typical shift.

On November 3, 2020, ToxStrategies collected PBZ air samples at Air Operations in Pacoima, California. The results of the air sampling at Air Operations are provided in Attachment 1.

- PBZ air samples for eight helicopter mechanics performing intermediate and/or heavy maintenance on the aircraft were analyzed for hexavalent chromium. Hexavalent chromium was detected in only one of eight samples (0.084 μg/m³) just above the detection limit (<0.081 μg/m³ [ToxStrategies, Inc., 2020d]; Attachment 1-A).
- PBZ air samples for six helicopter mechanics performing heavy maintenance on aircraft were analyzed for respirable crystalline silica, as quartz, cristobalite, and tridymite (Attachment 1-B). Crystalline silica was not detected in these samples.
- PBZ air samples for six helicopter mechanics performing intermediate maintenance on the aircraft were analyzed for benzene, ethylbenzene, and naphthalene. These chemicals were not detected in any samples (Attachment 1-C).
- Two area air samples were collected to assess general concentrations in the hangar compared to those for the specific workers: one in the hangar along the southwest wall and one in the work area (Attachment 1-C); the samples were analyzed for benzene, ethylbenzene, and naphthalene. These chemicals were not detected in either sample (Attachment 1-C).

On November 3, 2020, PBZ air samples for two equipment maintenance workers in the small engine repair shop, which is part of the Breathing Apparatus Shop, were analyzed for benzene, ethylbenzene, naphthalene, styrene, acetaldehyde, and formaldehyde. Only benzene, acetaldehyde, and formaldehyde were detected in both samples analyzed (Attachment 2-A).

On November 4, 2020, ToxStrategies collected PBZ air samples at the Eastern Fire Shop. The results of the air sampling at the Eastern Fire Shop are provided in Attachment 3.

• PBZ air samples for six fire equipment mechanics performing maintenance on the fire apparatus were analyzed for benzene, ethylbenzene, naphthalene, tetrachloroethylene, and diesel particulate matter (DPM). (Note that elemental carbon is the surrogate analyte for DPM.) Benzene, ethylbenzene, and naphthalene were not detected. Elemental carbon was detected in one sample at 180 μg/m³ but was not detected in any of the other samples at detection limits <2.5 μg/m³. It is likely that this single detection of elemental carbon does not represent diesel particulates but, rather, reflects the grinding of carbon in the steel during that day by the specific employee on which the sample was collected. For this reason, this concentration will not be evaluated in the risk assessment, because elemental carbon is not classified as a carcinogen. These results are presented in Attachment 3-A. Tetrachloroethylene was detected in all six samples, and these results are presented in Attachment 3-B.

- PBZ air samples for two fire equipment mechanics were analyzed for weldingfume metals<sup>1</sup> and hexavalent chromium during MIG (metal inert gas) welding, grinding, and cutting. Of the six metals included in the welding-fume panel, only cobalt and nickel were detected. The sample results are provided in Attachment 3-C for welding-fume metals and Attachment 3-D for hexavalent chromium.
- PBZ air samples for fire equipment mechanics performing maintenance on the fire apparatus were analyzed for N,N-dimethyl-para-toluidine, which was not detected in either sample (Attachment 3-E).
- Two area samples<sup>2</sup> at the Eastern Fire Shop were analyzed for benzene, ethylbenzene, naphthalene, and DPM, which were not detected (Attachment 3-A).

#### 2.2 Surface Sampling

Surface wipe sampling at Air Operations and the Breathing Apparatus Shop was conducted on November 3, 2020.

#### At Air Operations:

- PAHs, arsenic, and lead were analyzed in wipe samples from 12 random locations on Firehawk and Bell412 aircraft, which were parked inside the hangar for heavy maintenance and outside on the flight line. Only lead was measurable in any of these samples (Attachment 1-D-1 and 1-D-3).
- Smaller numbers of additional wipe samples were collected from various locations on Firehawk and Bell412 aircraft parked outside on the flight line. The samples were analyzed for hexavalent chromium (six samples from the aircraft engine; two samples from Mastinox-coated surfaces) and chlorinated dioxins/furans and PCBs (two samples). Hexavalent chromium, chlorinated dioxins/furans, and PCBs were detected in all samples analyzed (Attachment 1-D-2 and 1-D-4).

At the Breathing Apparatus Shop, wipe samples were collected from the air packs and fire hoses that were being repaired.

• A total of six samples were collected from field air packs and training air packs. These samples were analyzed for arsenic, lead, naphthalene, and PAHs; lead, naphthalene and PAHs were detected (Attachment 2-B-1 and 2-B-3). Two samples were analyzed for pentachlorophenol, chlorinated dioxins/furans, and

The welding-fume metals that are carcinogens include arsenic, beryllium, cadmium, cobalt, lead, and nickel.

One area sample was collected in the center third aisle column (from the south entrance), and one sample was collected in the third bay along the west side (on the work bench).

PCBs (Attachments 2-B-1 and 2-B-2). Chlorinated dioxins/furans and PCBs were detected in both samples. Lead, chlorinated dioxins/furans, and PCBs were detected in both the training and field air packs; PAHs were detected in the training air packs only. Arsenic and pentachlorophenol were not detected in any of the wipe samples collected on the air packs.

• Wipe samples were also collected on the exterior locations of used fire hoses at six locations. PAHs, arsenic, and lead were analyzed in wipe samples, but only lead was detected (in all six samples). The results are presented in Attachment 2-C-1 and 2-C-2.

Surface wipe sampling at the Eastern Fire Shop was conducted on November 4, 2020. PAHs, chlorinated dioxins/furans, PCBs, pentachlorophenol, lead, and arsenic were analyzed in wipe samples from various locations on the fire truck. Only lead, chlorinated dioxins/furans, and PCBs were detected. The results are presented in Attachment 3-F-1, 3-F-2, and 3-F-3.

#### 2.3 Chemicals of Potential Concern

For fire mechanics, COPCs are those carcinogenic chemicals that are associated with exposure related to the work activities. COPCs for this project were identified by location/SEG combination and by each medium (air or surfaces). Chemicals detected in at least one sample were identified as COPCs for a specific location and medium. Chemicals that were analyzed but not detected in any samples were evaluated in the uncertainty assessment.

#### 2.3.1 Air Operations

Hexavalent chromium was detected in one or more samples and is considered a COPC in air at this location for this risk assessment. Hexavalent chromium, lead, PCBs, and dioxin/furans were detected and are considered COPCs on various equipment surfaces for this location. In addition, hexavalent chromium was detected on Mastinox-coated surfaces on the aircraft.

#### 2.3.2 Breathing Apparatus Shop

Benzene, acetaldehyde, and formaldehyde were detected in one or more samples and are considered COPCs in air at the small engine repair shop. Lead, PAHs, PCBs, and dioxins/furans were detected and are considered COPCs on air-pack surfaces for this location/SEG. Only lead was detected on fire hoses, which will be evaluated as a COPC for this location/SEG.

#### 2.3.3 Eastern Fire Shop

Tetrachloroethylene was detected in one or more air samples and is considered a COPC in air for this location. In addition, PBZ air samples were collected to characterize inhalation exposure for a welder. Cobalt and nickel were detected in one or more air samples and are considered COPCs in air for this location/SEG. Lead, PCBs, and dioxins/furans were detected on surfaces and are considered COPCs on surfaces for this location.

#### 3 Exposure Assessment

Exposure assessment is the process by which the sources of chemicals, their transport mechanisms, relevant exposure routes, and receptors are identified. The receptors in this analysis are the workers in each of the SEGs. The sources of chemicals are the products used or the equipment with which the workers have contact or otherwise interact when conducting maintenance tasks. The chemicals may be released to air and onto surfaces related to worker activities. Exposure routes for helicopter mechanics, equipment maintenance workers, and fire equipment mechanics are inhalation, dermal absorption, and incidental ingestion.

#### 3.1 Similar Exposure Groups

Each of the primary SEGs identified in the qualitative exposure assessment report (Task 2; ToxStrategies, Inc., 2020c) applicable to this exposure assessment is described in general in this section.

#### 3.1.1 Helicopter Mechanic / Helicopter Maintenance Inspector

Heavy maintenance of the aircraft typically takes place inside the hangar, and the mechanics generally wear a uniform, work boots, goggles/safety glasses, hearing protection, gloves (type dependent on task), and knee pads.

Intermediate maintenance on the aircraft takes place on a daily basis and can take approximately an hour to complete. This job is usually conducted outdoors on the flight line, and personal protective equipment (PPE) includes work boots, work uniform, goggles/safety glasses, hearing protection, gloves (dependent on task), and knee pads.

Painting, priming, and sanding of aircraft components can take place in the paint booth, inside the hangar, or outside in the open air, depending on the aircraft component. The mechanic may use a variety of different paints, paint strippers, primers, and enamels. Depending on the paint job, it could take 30 minutes or less and be performed once per week, or it could take 10 hours a week and be performed for 40 hours a month. For the major paint jobs, the Helicopter Maintenance Inspector is the primary painter. His work typically takes place in the paint booth, with installed exhaust filters, using an airline respirator.

#### 3.1.2 Equipment Maintenance Worker

At the small engine repair shop, worker tasks include equipment examination and analysis of equipment malfunctions or mechanical failure. Other tasks include tuning up equipment used by the County fire stations, such as rescue tools, lawn mowers, vacuums, and generators.

At the fire hose repair shop, the workers are responsible for repairing fire-truck hoses and completing the hose test. Equipment, such as firefighter air packs, is maintained and tested at the Breathing Apparatus Shop (Pacoima). Air packs used during fire training in

simulated structure burns, such as that conducted at the Los Angeles County Fire Department Fire Station 129 in Lancaster, are maintained at the Breathing Apparatus Shop. The workers' PPE includes latex gloves and an apron.

#### 3.1.3 Fire Equipment Mechanic

The shop-assigned fire equipment mechanics (FEMs) at either the Eastern Fire Shop or the North County Fire Shop conduct daily maintenance of the fire apparatus, which is a highly variable job task and encompasses a wide range of products and tools. Shop-assigned FEMs typically work on the major repairs such as engine and transmission changes, inframe engine rebuilds, differential exchanges and rebuilds, major pump repair, plumbing issues, and water tank removal, and they are required to do a significant amount of welding to repair or replace some parts. Both shop locations have facilities with roll-up doors and a diesel exhaust capture system that can be used when the apparatus is running inside the building, but those systems do not operate when the vehicles are moving in and out of the shop. The Eastern Fire Shop also has side-wall vents that exhaust air out of the building. FEMs may use a combination of a face shield, gloves (rubber or latex/nitrile), N95 respirator, and work boots when performing their job task. The daily maintenance of the fire apparatus occurs during the entire workday, every day.

Depending on the number of wildfires that occur each year, the field-assigned FEMs may get called to a wildfire base camp<sup>3</sup> for approximately 2-week durations, 24 hours per day. During this time, the assigned FEMs are required to stay onsite for the assigned period and are responsible for repairing any fire apparatus or fire equipment that is needed. Further, field-assigned FEMs may also get called to a fire site. Although this occurs infrequently (approximately once every three years), the field-assigned FEM is responsible for needed fire apparatus repairs anywhere, at any time. Therefore, there are no exposure bounds for this group of workers, and the level of PPE provided (work boots, work uniform, gloves, eye protection, N95 respirator) is less than that provided to the firefighters.

#### 3.2 Exposure Points and Exposure Pathways

The following primary SEGs and locations were evaluated to quantify exposure:

- Intermediate and heavy maintenance on aircraft at Air Operations
- Repair and tune-up of power equipment at the small engine repair shop (Breathing Apparatus Shop)
- Maintenance/repair on fire apparatus at the Eastern Fire Shop.

\_

The outdoor base camps are a mobilization and staging area for firefighters and support personnel during a large wildfire.

For each of these SEGs, there are three relevant exposure pathways:

- Inhalation of air in the workplace, which is based on measurements from PBZ air samplers
- Dermal contact with residues on surfaces, which is based on measurements from relevant surfaces
- Incidental ingestion of residues on surfaces, which is based on measurements from relevant surfaces.

In addition, exposures were evaluated for SEGs that addressed specific activities that were not addressed by the SEGs described above. Typically, these additional exposures were different, because exposure rates were lower than for the primary SEGs, based on lower exposure frequencies or lower surface concentrations. The following activities/SEGs were evaluated separately.

- Contact with Mastinox during intermediate and heavy maintenance on aircraft at Air Operations, resulting in dermal contact and incidental ingestion exposures
- Fire hose repair at the fire hose repair shop (Breathing Apparatus Shop), resulting in dermal contact and incidental-ingestion exposures (air samples were not collected)
- Air pack repair at the Breathing Apparatus Shop, resulting in dermal contact and incidental-ingestion exposures (air samples were not collected)
- Welding/grinding/cutting activities during maintenance and repair on fire apparatus at the Eastern Fire Shop, resulting in inhalation exposures (air samples were collected for welding workers during the work day).

#### 3.3 Exposure Quantification

Exposure was quantified for each of the exposure pathways based on assumptions relevant to the SEGs. Because the cancer potency values are developed for continuous exposure over the course of a lifetime, it is appropriate to calculate the fraction of a lifetime that mechanics are exposed for each SEG. Table 2 summarizes exposure assumptions for each exposure pathway discussed further in this section.

#### 3.3.1 Inhalation Exposure

Inhalation exposure was calculated using the following equation:

$$Inhalation \ Exposure = \frac{Ca}{PF} \times ET_f \times EF \times ED$$

Assumptions for each parameter are described below.

Inhalation Exposure (micrograms per cubic meter ( $\mu g/m^3$ ): Average air concentration based on frequency and duration of exposure.

Concentration in air (Ca;  $\mu$ g/m³): Concentration in air was measured for each SEG. These are discussed further in Section 2.1, above.

**Protection Factor (PF; unitless):** A protection factor is used to adjust inhalation exposure when a respirator is used to protect the employee from exposure. An N95 half-mask respirator is used for welding activities, and thus, a protection factor of 10 was used for this exposure (CCR, Title 8, §5144. Respiratory Protection). All other SEGs were evaluated assuming that no respirator was used (a protection factor of 1).

**Exposure Time Ratio (ET\_f; hours/hours):** This is the time that a worker spends per day exposed to chemicals in air. The exposure time ratio for SEGs at Air Operations and the Eastern Fire Shop is 9 hours per 24-hour day, based on the standard work week at these locations, resulting in an exposure time ratio of approximately 0.38. The exposure time ratio for SEGs at the Breathing Apparatus Repair Shop was 8 hours per 24-hour day based on the standard work week, resulting in an exposure time ratio of approximately 0.33.

**Daily Exposure Frequency Ratio (EF; days/days):** Exposure frequency is the number of days averaged over one year that a worker is exposed. For air exposures, exposure frequency is considered to be the number of days exposed out of a 365-day year. Three SEGs had different exposure frequencies based on site-specific information provided to ToxStrategies:

- Exposure frequency for Air Operations (EF\_1) was based on working 9 days over 2 weeks (9 days/2 weeks \* 50 weeks, or 225 days per year). The 50 weeks total excludes 2 weeks of vacation. Air Operations SEGs also put in up to 500 hours of overtime, which is approximately an additional 55 nine-hour days, for a total of 280 days per year, resulting in an exposure frequency ratio of 0.77.
- Exposure frequency for the Breathing Apparatus Shop (EF\_2) was based on working 5 days per week for one year (5 days/week \* 50 weeks, or 250 days). Breathing Apparatus Shop SEGs also put in up to 100 hours of overtime, which is approximately twelve 8-hour days, for a total of 262 days per year, resulting in an exposure frequency ratio of 0.72.
- Exposure frequency for the Eastern Fire Shop (EF\_3) was based on working 9 days per 2 weeks (9 days/2 weeks \* 50 weeks, or 225 days). Eastern Fire Shop SEGs also put in up to 200 hours of overtime, which is approximately twenty-two 9-hour days, for a total of 247 days per year, resulting in an exposure frequency ratio of 0.68.

**Exposure Duration Ratio (ED; years/years):** Workers are assumed to work for 45 years out of a 70-year lifetime (0.64) (NIOSH, 2017). This may be an overestimation for the working tenure of most mechanics evaluated as part of our survey of Los Angeles County because the County hires trained mechanics, e.g., in Air Operations, all mechanics had at least 10 years of experience before qualifying to work for the county Fire Department.

#### 3.3.2 Dermal Contact

Dermal contact occurs when mechanics contact surfaces covered with residues containing chemicals of interest. Site-specific assumptions (Table 2) and chemical-specific dermal absorption factors selected from the scientific literature (Table 3) were used to evaluate potential dermal absorption through the skin. Potential dermal contact was calculated as:

$$Dermal\ Contact\ Exposure = \left(\frac{Csw \times CF \times SAf \times Abs \times EV \times EF \times ED\_y}{ATca \times BW}\right)$$

Dermal Contact Exposure (milligram per kilogram per day [mg/kg-day]): Amount of daily chemical exposure per kilogram body weight.

Concentration on surface wipe (Csw; micrograms per square centimeter  $[\mu g/cm^2 - event]$ ): Potential concentrations on the surface of the skin were estimated using surface wipe sample results. The results are discussed in Section 2.2, above.

Conversion Factor (CF; milligrams per micrograms [mg/ $\mu$ g]): Concentrations on the surface wipes were converted from  $\mu$ g to mg using a factor of 0.001.

Surface area of fingers (SAf; square centimeters [cm²]): All SEGs wear gloves while working. However, there are tasks for which gloves may not worn, and gloves also can tear. To estimate the surface area for the portion of the hand subject to dermal exposure, we used 19 cm², based on assumptions provided by the Office of Environmental Health Hazard Assessment (OEHHA) in their interpretive guidelines for safe use determinations concerning lead fishing weights (OEHHA, 2008). The area is equal to the surface area of the first three fingers of the palmar surface for both male adult hands.

**Percent absorption (Abs; %):** Percent absorption is a chemical-specific property. Details from the literature review used to develop these values is presented in Attachment 4. Table 3 summarizes these chemical-specific factors.

Event frequency (EV; events per day): To be conservative in this assessment, we have assumed that dermal contact occurs once per hour. Based on observations during visits to the facilities, torn gloves or activities that are performed without gloves that allow for direct contact with surfaces may not occur as often as once per hour. At the rate of one contact per hour, SEGs at Air Operations and the Eastern Fire Shop who work 9 hours per day would have 9 contacts per day. SEGs at the Breathing Apparatus Shop who work 8 hours per day would have 8 contacts per day. SEGs who contact Mastinox at Air Operations would have one contact per day, based on information provided to ToxStrategies.

**Exposure Frequency (EF; days per year):** Consistent with the discussion of inhalation exposures, exposure frequency is a combination of typical work schedules and overtime hours. As described for inhalation exposure (Section 3.3.1), the exposure frequencies are as follows:

• Air Operations — 280 days per year

- Breathing Apparatus Shop 262 days per year
- Eastern Fire Shop 247 days per year.

Additionally, SEG-specific exposure parameters were developed for the purpose of assessing dermal exposure to Mastinox on aircraft parts at Air Operations. Based on information provided to ToxStrategies, exposure frequency for contacting Mastinox is estimated to be 14 days per month for 12 months, resulting in 168 days per year.

**Exposure Duration (ED; years):** Workers are assumed to work for 45 years (NIOSH, 2017).

**Body weight (BW: kilograms [kg]):** Body weight for an adult worker is assumed to be 80 kg (DTSC, 2019).

**Averaging Time for carcinogens (ATca; days):** The averaging time for carcinogenic risk assessments is 70 years, or 25,550 days (70 years \* 365 days) (DTSC, 2019).

#### 3.3.3 Incidental Ingestion Exposure

Incidental ingestion occurs when fire mechanics contact surfaces with residues on the surface that contain chemicals of interest and then touch their hands to their mouths. Those chemicals from the residues can adhere to their hands, and subsequently, the particles can be ingested. Site-specific and general assumptions were used to evaluate potential incidental ingestion (Table 2). Chemical-specific relative bioavailability (RBA) via ingestion exposure was also included (Table 3). Incidental ingestion in this scenario is based on the same residue levels estimated for dermal absorption. A portion of the chemical (up to 25% depending on the chemical; Table 3) is potentially absorbed through the skin based on the chemical-specific dermal absorption factors. The remaining 75% is available for incidental ingestion, which is greater than the approximately 50% that is estimated to transfer from the fingers to the mouth. Therefore, the residue on the fingertips is sufficient for both the dermal and incidental ingestion pathways.

Potential incidental ingestion was calculated as follows:

$$Incidental\ Ingestion\ Exposure \\ = \left(\frac{Csw \times CF \times SAf \times Fdirect \times RBA \times \gamma - d \times ET_{hours} \times EF \times ED\_y}{ATca \times BW}\right)$$

**Incidental Ingestion Exposure (mg/kg-day):** Daily exposure amount per kilogram body weight.

Concentration on surface wipe (Csw; micrograms per square centimeter [µg/cm²]): Potential concentration on the surface of the skin was measured using surface wipe sampling. The results are discussed in Section 2.2.

Conversion Factor (CF; milligrams per micrograms [mg/ $\mu$ g]): Concentrations on the surface wipes were converted from  $\mu$ g to mg using a factor of 0.001.

Surface area of fingers (SAf; square centimeters [cm<sup>2</sup>]): Consistent with the assumptions for dermal exposure, all SEGs wear gloves while working. However, there are tasks for which gloves may not be worn, and gloves can tear. To estimate the surface area for the portion of the hand subject to dermal exposure and subsequent ingestion, we used 19 cm<sup>2</sup>, based on assumptions provided by OEHHA in their interpretive guidelines for safe use determinations for lead fishing weights (OEHHA, 2008). The area is equal to the surface area of the first three fingers of the palmar surface for both male adult hands.

**Direct Transfer Factor (Fdirect):** OEHHA's interpretive guideline estimates that 50% (0.5) of the chemical on the relevant part of the hand is transferred from the hands to the mouth (OEHHA, 2008).

**Relative bioavailability (RBA):** Relative bioavailability is a chemical-specific property that relates the amount of a chemical that is systemically available after ingestion to the amount of chemical that was systemically available in the oral toxicity testing. USEPA has developed default RBAs for arsenic and lead in soil (USEPA, 2021a,b) that have been applied herein. The RBA for all other chemicals was assumed to be 100%.

Number of Contacts per Hour ( $\gamma$ -d): Consistent with the assumptions for dermal exposure, we have assumed that dermal contact occurs once per hour, which assumes that gloves aren't worn or are torn once per hour. This is conservative, based on observations during visits to the facilities: torn gloves or activities that are performed without gloves may not occur as often as once per hour.

**Exposure Time (ET; hours per day):** SEGs at Air Operations and the Eastern Fire Shop work 9 hours per day, and at one contact per hour, would have nine contacts per day. SEGs at the Breathing Apparatus Shop work 8 hours per day, and at one contact per hour, would result in eight contacts per day. SEGs that contact Mastinox at Air Operations would have one contact per day, based on the information provided to ToxStrategies.

**Exposure Frequency (EF; days per year):** Consistent with the discussion for dermal contact exposures, exposure frequency is a combination of typical work schedules and overtime hours. As described for dermal contact exposure (Section 3.3.2), the exposure frequencies are as follows:

- Air Operations 280 days per year
- Breathing Apparatus Shop 262 days per year
- Eastern Fire Shop 247 days per year.

Additionally, for the purpose of assessing dermal exposure, surface samples were collected from Mastinox on aircraft parts at Air Operations. Based on information provided to Tox-Strategies, exposure frequency for contacting Mastinox is estimated to be 168 days per year.

**Exposure Duration (ED; years):** Workers are assumed to work for 45 years (NIOSH, 2017).

**Body weight (BW: kilograms [kg]):** Body weight for an adult worker is assumed to be 80 kg (DTSC, 2019).

**Averaging Time for carcinogens (ATca; days):** The averaging time for carcinogenic risk assessments is 70 years or 25,550 days (70 years \* 365 days) (DTSC, 2019).

#### 3.4 Exposure-Point Concentrations

Exposure-point concentrations for each medium (air and surfaces) were developed for each SEG/location. Chemicals that were detected in at least one sample of air or one surface wipe were considered COPC for the purpose of this risk assessment. Chemicals that were never detected were evaluated separately for the uncertainty assessment, to understand whether the detection limits were sufficiently low for eliminating the need to further evaluate risk (Section 5.1.3)

Exposure point concentrations were calculated as follows:

- If a chemical was detected in at least one sample and analyzed in at least five samples, the exposure-point concentration was the average of all the sample results. One-half the detection limit was used to substitute for non-detect values when calculating the average (AIHA, 2015).
- If a chemical was detected in at least one sample and analyzed in fewer than five samples of a specific medium, the maximum detected concentration was used as the exposure-point concentration in the absence of sufficient data to calculate a representative average.

A summary of the exposure-point concentrations is presented in Table 4 for personal breathing-zone samples and in Table 5 for surface wipe samples.

#### 4 Toxicity Assessment

This toxicity assessment provides the quantitative measures, termed cancer potency or unit risks, used to estimate the increased risk of developing cancer based on the cumulative exposure to carcinogens estimated over the working lifetime of fire mechanics, as quantified in Section 3. The DIR requested that cancer potency and unit risk estimates be developed using guidance from California agencies as the first preference For some of the COPCs, cancer potency criteria were readily available for potential carcinogenic health effects. For others, a review of regulatory references did not provide information that was appropriate for use in a quantitative estimate of potential cancer risks.

#### 4.1 Chemicals with Available Cancer Potency Criteria

Toxicological values and information regarding the potential for carcinogenic effects in humans were obtained from a hierarchy of regulatory references, beginning with California's regulations for toxicity criteria for human health risk assessment (California Code of Regulations, Title 22, Sections 68400.5, 69020-69022), followed by other California guidance and USEPA references. These references provide chemical-specific toxicity data that represent consensus within the regulatory agency. In cases for which insufficient data were available from California sources, guidance from the federal EPA, OSHA and NIOSH were used.

The complete hierarchy of sources reviewed is as follows:

- 1. California's Toxicity Criteria for Human Health Risk Assessment (California Code of Regulations [CCR], Title 22, Sections 68400.5, 69020-69022)
- 2. OEHHA, 2011a, Technical Support Document for Cancer Potency Factors: Methodologies for derivation, listing of available values, and adjustments to allow for early life stage exposures.
- 3. OEHHA, Public Health Goals (e.g., 2011b)
- 4. OEHHA, Expedited Cancer Potency Factor (1992)
- 5. USEPA's IRIS database (USEPA, 2020b)
- 6. USEPA's Provisional Peer Reviewed Toxicity Values (PPRTVs) (e.g., USEPA, 2008)
- 7. Other toxicity values includes additional USEPA and non-USEPA sources of toxicity information. Non-USEPA sources include the ATSDR (https://www.atsdr.cdc.gov). USEPA sources include the most current Health Effects Assessment Summary Tables (HEAST; USEPA, 1997).

In risk assessment, quantitative values are used to estimate an upper-bound probability of an individual developing cancer as a result of a lifetime of exposure to a particular level of a potential carcinogen. Specifically, for inhalation exposures, an inhalation unit risk value (IUR) is developed similarly and represents the risk associated with exposure to  $1 \mu g/m^3$  of a chemical in air; IURs are expressed in units of  $(\mu g/m^3)^{-1}$ . For non-inhalation pathways, a slope factor (SF) is a plausible upper-bound estimate of the probability of a response per unit intake of a chemical over a lifetime, which is the 95% upper confidence limit (UCL) of the slope of the dose-response curve expressed in units of the inverse of milligrams per kilogram-day  $(mg/kg-day)^{-1}$ . Tables 6 and 7 present the cancer toxicity criteria for inhalation and oral/dermal exposures, respectively.

#### 4.2 Adjustment to Oral Slope Factors for Dermal Exposure

For dermal exposure, the exposure assessment results in an estimate of absorbed dose. However, oral toxicity criteria, which are typically used to assess risk from dermal exposure, are typically based on administered dose. The difference between administered and

absorbed dose in the development of oral toxicity criteria can result in an underestimation of potential health risks from dermal exposure (USEPA, 2004). Oral toxicity criteria based on an administered dose may therefore need to be adjusted to account for the difference between the administered dose in the critical study (which formed the basis of the toxicity criterion) and the absorption efficiency of the chemical in question. The oral toxicity criteria can be adjusted and applied appropriately to dermal exposures. Table 3 presents the oral-to-dermal adjustment factor (fraction of contaminant absorbed in gastrointestinal tract; GIABS) for the COPCs.

#### 5 Risk Characterization

In this section of the risk assessment, toxicity and exposure assessments are integrated into quantitative expressions of theoretical increased carcinogenic risks. Increased cancer risk estimates are quantified for SEGs based on the estimated exposures to measured carcinogens. An uncertainty analysis is included to address areas of the risk estimates that may over- or underestimate risks. Qualitative discussions of SEGs that could not be evaluated are also included.

#### 5.1 Quantitative Estimate of Theoretical Increased Cancer Risks

The estimates of increased risk for individual COPCs and exposure pathways are presented in spreadsheets contained in Attachment 5. Risks are characterized by location and SEG (e.g., Eastern Fire Shop, welding). For quantitative estimates of potential increased cancer risk, the calculated risk associated with exposure to surface dust and air are summed to estimate cumulative risk. Theoretical excess cancer risks were calculated for each carcinogen where detectable concentrations of a chemical were measured and quantitative cancer potency values were available. Cases where one or the other of these factors were unavailable are discussed in Section 5.2. Consistent with regulatory policy, our risk assessment assumes no threshold for carcinogenicity, meaning there is no exposure level at which there is no increased risk of cancer. These risks are not measurable and therefore only theoretical model-based estimates. As such, the calculated increased risks estimates developed herein are compared with risk ranges that have been considered acceptable by regulatory agencies charged with risk management.

Typically, excess cancer risk for occupational exposures is determined to be significant if the risk for a working population exceeds 1 in 1,000. This threshold for significance has been used by OSHA for nearly 20 years following the Supreme Court decision in *American Petroleum Institute v. Industrial Union Department* [448 U.S. 607 (1980)] (commonly referred to as the Benzene decision), wherein the court concluded that a reasonable person might regard a lifetime cancer risk of 1 in 1,000 as significant, yet might regard a risk of 1 in 1,000,000,000 as trivial. As such, current regulatory occupational exposure limits (OELs) for carcinogenic substances such as the OSHA PELs were developed with the 1 in 1000 threshold. Recent NIOSH Recommended Exposure Limits (RELs), including that hexavalent chromium (NIOSH, 2013) and titanium dioxide (NIOSH, 2011) have been based on an excess cancer risk rate of 1 in 1,000 but also considered technical feasibility.

While the Supreme Court decision established that cancer risk greater than 1 in 1,000 is significant, it did not conclude that risks between 1 in 1,000 and 1 in 1,000,000,000 are insignificant. Risk managers often judge "acceptable risks" to be those in the range of 1 in 10,000 to 1 in 1,000,000. Recently, NIOSH updated its Chemical Carcinogen Policy and will establish Risk Management Limits for Carcinogens at air concentrations that correspond to the 95<sup>th</sup> percentile lower confidence limit of the 1 in 10,000 risk estimate (NIOSH, 2017). Similarly, DIR indicated that their goal is 1 in 10,000 (personal communication, Eric Berg, January 26, 2021). Therefore, for the purpose of this risk assessment, excess cancer risks calculated to be less than 1 in 10,000 have been judged *de minimus*.

#### 5.1.1 Quantifying Increased Cancer Risk

The calculated increase cancer risks are estimated as the additional probability of an individual developing cancer over a lifetime as a result of exposure to a potential carcinogen. For example, the same potential risk could be described as one additional case out of ten thousand people exposed under the assumptions evaluated, e.g., 1 of 10,000 workers with SEG exposures for 45 years. For consistency with the target level discussed above, cancer risk is presented in terms of the number of cases out of 10,000 people exposed. Predicted carcinogenic risk estimates are generally an upper-bound value, because assumptions are typically made to intentionally overestimate potential exposure and toxicity.

For inhalation pathways, the average daily air concentration is converted to estimates of risk using the IUR value. Estimated daily intakes averaged over a lifetime of exposure are converted to estimates of risk using the slope factor for oral exposures (SFO) for non-inhalation pathways (mg/kg-day)<sup>-1</sup>.

For inhalation exposures, cancer risk is calculated as follows:

Lifetime Excess Cancer Risk – inhalation $_i = LAC_i \times IUR_i$ 

where:

LAC<sub>i</sub> = lifetime average concentration for chemical "i" (µg/m<sup>3</sup>)

 $IUR_i$  = inhalation unit risk value for chemical "i" ( $\mu g/m^3$ )<sup>-1</sup>

For non-inhalation exposures, cancer risk is calculated as follows for the dermal and ingestion pathways, respectively:

Lifetime Excess Cancer Risk – 
$$derm_i = LADD$$
- $dermal_i \times SFO_i/GIABS_i$   
Lifetime Excess Cancer Risk –  $ing_i = LADD$ - $ing_i \times SFO_i$ 

where:

LADD-derm<sub>i</sub> = lifetime average daily dose from dermal exposure for chemical

"i" (mg/kg-day)

LADD-ing<sub>i</sub> = lifetime average daily dose from ingestion exposure for chemi-

cal "i" (mg/kg-day)

SFO<sub>i</sub> = slope factor (oral) for chemical "i"  $(mg/kg-day)^{-1}$ 

GIABS<sub>i</sub> = fraction of contaminant absorbed in gastrointestinal tract for

chemical "i" (unitless)

The excess cancer risks for each chemical and exposure route are summed, regardless of tumor site (e.g., stomach cancer, lung cancer) to estimate the total excess cancer risk for the exposed individual:

Cumulative Lifetime Excess Cancer Risk

$$= \sum_{i=1}^{n} (Lifetime\ Excess\ Cancer\ Risk - inhalation_i)$$

+ Lifetime Excess Cancer Risk - non - inhalation<sub>i</sub>)

#### 5.1.2 Results of Carcinogenic Risk Assessment

Potential cancer risks were estimated for the inhalation, dermal, and incidental ingestion pathways, and cumulative lifetime excess cancer risk was summed as described in Section 5.1.1. The results are summarized in Table 8, and the detailed calculations are presented in Attachment 5. As shown in Table 8, the highest predicted risks resulted from inhalation exposure. Predicted risks from dermal contact and incidental ingestion were well below a target level of 1 excess cancer case in 10,000 workers in a 45-year working lifetime.

#### 5.1.2.1 Predicted Cancer Risks for Primary SEGs

Predicted theoretical excess cancer risks for inhalation exposure over a 45-year working lifetime for the primary SEGs as follows, with the primary chemical noted in the parentheses:

- 20 in 10,000 (0.2%) at Air Operations (hexavalent chromium)
- 30 in 10,000 (0.3%) at the small engine repair shop at the Breathing Apparatus Shop (benzene)

• 400 in 10,000 (4%) at the Eastern Fire Shop (tetrachloroethylene).

Another way to put these risks in context is to compare them to IARC's monograph that reviewed the carcinogenicity of firefighting (IARC, 2010). After the IARC Working Group summarized 42 epidemiologic studies of firefighting occupation and cancer risk (19 cohorts, 11 case-control studies, and 14 "other" studies) using meta-analyses for specific tumor types, persons who had ever held the occupation of a firefighter were found to be at a statistically significant increased risk of testicular cancer, prostate cancer, and non-Hodgkin's lymphoma compared to persons who had never been a firefighter (2010). The IARC Working Group's analysis of firefighters found that:

- There was an approximately ~50% increased risk of testicular cancer among firefighters compared with non-firefighters
- There was an approximately ~30% increased risk of prostate cancer among firefighters compared with non-firefighters
- There was an approximately ~20% increased risk of non-Hodgkin's lymphoma among firefighters compared with non-firefighters (IARC, 2010).

These estimates represent risk of cancer calculated using observational data of cancer rates among firefighters, rather than the theoretical risk estimates calculated herein for helicopter mechanics, equipment maintenance workers, and fire equipment mechanics. The theoretical estimated risks for the workers identified in this study are considerably lower than that measured among firefighters (0.2%-4% vs. 20-50%). As a point of reference, the risk of developing cancer at some point during their lifetime for persons in the US is approximately 39.5% (NCI, 2020). Note that this risk is baseline, not increased risk which is above baseline.

#### 5.1.2.2 Predicted Cancer Risks for Specific Activities

In addition to calculating risks for primary SEGs, some activity-specific risks were also calculated (Table 8). Theoretical excess cancer risks over a 45-year working lifetime were calculated by specific exposure routes for the following additional activities:

- Contact with Mastinox at Air Operations 0.3 in 10,000
- Inhalation of particles from welding/grinding/cutting activities at the Eastern Fire Shop 0.02 in 10,000
- Contact with residue on air packs at the Breathing Apparatus Shop 0.2 in 10,000
- Contact with residue on fire hoses at the fire-hose repair shop (part of the Breathing Apparatus Shop) 0.001 in 10,000

In all four cases, exposure was below the target level of 1 in 10,000.

#### 5.1.3 Uncertainties in the Quantitative Cancer Risk Assessment

In any risk assessment, estimates of potential carcinogenic risk and noncarcinogenic health effects have numerous associated uncertainties. Uncertainty is part of all four areas of risk assessment: the hazard identification/data evaluation, exposure assessment, toxicity assessment, and risk characterization. In this section, these uncertainties are discussed qualitatively, including whether the uncertainty may result in overestimation or underestimation of risk. For example, there is uncertainty in the toxicity criteria for the various COPCs, but those toxicity criteria are developed using conservative assumptions to ensure they are protective, and they are likely to overestimate actual risk.

#### 5.1.3.1 Hazard Identification/Data Evaluation

The focus of this risk assessment was on exposure to chemicals identified as carcinogens based on the evaluations in Tasks 1 and 2 and analyzed in Task 4 (ToxStrategies, 2020b,c,d). Specific chemicals of interest were evaluated for each SEG and location based on the *qualitative* risk ranking results conducted in Task 2. Specifically, all chemicals considered to present a qualitatively very high, high, or moderate potential risk were included in the assessment, and those considered trivial were not. However, given the very low potential for exposure to the excluded chemicals, the theoretical excess cancer risks have not been underestimated significantly.

Risks potentially associated with exposure to some chemicals identified in Task 2 could not be calculated because of the absence of regulatory toxicity criteria. Potential exposure to these chemicals is discussed qualitatively in Section 5.2.4.

#### 5.1.3.2 Exposure Assessment

Chemicals of potential concern were identified as those chemicals detected in at least one sample. Many chemicals were not detected in any samples and were reported as below a detection limit. To evaluate whether the detection limit was adequate for assessing potential risk, the same risk calculations applied to the detected concentrations were applied to the detection limits for those chemicals that were not detected in any samples (Attachment 5). The limits of detection used in this analysis are identified as exposure point concentrations in Attachment 1. As shown in Attachment 5-A, estimated risks for chemicals in PBZ samples at the detection limit ranged from 1 in 10,000 (diesel particulate matter) to 60 in 10,000 (naphthalene). This comparison demonstrates the very conservative nature of this assessment. Risk estimates associated with the detection limits are much lower than the maximum calculated risks, such that this uncertainty would not affect the conclusions of this report. For chemicals in surface wipe samples, only arsenic detection limits correspond to incidental ingestion risks (2 in 10,000) that are slightly above 1 in  $10.000.^{4}$ 

<sup>&</sup>lt;sup>4</sup> N,N-dimethyl-para-toluidine was not included in the evaluation of other chemicals that were not detected because an inhalation unit risk value was not available in the regulatory references for this chemical.

Crystalline silica was not detected in any of the PBZ air samples and did not have a IUR in the regulatory references. The lower bound of the detection limit for quartz ranged from 4.7 to  $6.4 \,\mu \text{g/m}^3$  which is approximately a factor of 10-fold lower than the OSHA PEL of  $50 \,\mu \text{g/m}^3$ . Theoretical excess cancer risk at the OSHA PEL for a working lifetime was calculated by OSHA as 5-23 cancers per 1,000 workers. As such the potential excess cancer risk at the limit of detection is approximately 5-23 in 10,000 workers (Federal Register, 2016).

Chemical concentrations were measured in multiple samples that were collected on the same day. This sampling approach addresses variability between workers and job tasks on a given day, but does not provide information on variability over time (e.g., different days). For example, the tetrachloroethylene concentrations are related to use of a specific NAPA® Lectra Clean® 3000 Energized Electrical Equipment Cleaner. Tetrachloroethylene contributed significantly to the calculated increased risk (360 in 10,000 in the Eastern Fire Shop). It is not known whether the use of the product on the sampling day was high, low, or equivalent compared to its use over time.

Exposure-point concentrations were the maximum detected concentrations for several chemicals because of the limited number of samples that were collected. These are identified in bold font in Tables 4 and 5. Use of the maximum concentration may overestimate potential exposures. For example, the maximum concentration of benzene used to estimate risk was detected in one of two samples at the Breathing Apparatus Shop (680  $\mu$ g/m³), which was more than twice the value of the other sample (300  $\mu$ g/m³).

Exposure assumptions were developed for the dermal contact and incidental ingestion exposure pathways that likely overestimated potential risk, because gloves are worn by the helicopter mechanics, equipment maintenance workers, and fire equipment mechanics when performing their tasks. Gloves may actually reduce the risk to 0, if there is no direct contact with the skin or opportunity for incidental ingestion. In the risk estimates, we assumed that the surfaces of three fingertips were uncovered eight to nine times per day (depending on the shift length). Even considering this overestimate for potential contact frequency, dermal contact and incidental ingestion were not considered significant exposure pathways with respect to potential carcinogenic risk.

One unique feature of the dioxin/furan and PCB TEQ concentrations used to estimate risk is that the total value for all congeners was calculated using one-half the detection limit to estimate the concentrations of congeners that were not detected. For many samples, the contribution to the TEQ from the congeners that were not detected was as high or higher than the contribution from the congeners that were detected. In general, this reflects the relatively low concentrations of these chemicals, which did not contribute significantly to theoretical risk.

Potential exposure for some SEGs could not be sampled, because the activities (specifically, painting/priming/sanding aircraft parts by a helicopter maintenance inspector at Air Operations and repair of fire apparatus by field-assigned mechanics at a wildfire base

camp) are intermittent and weren't occurring during sampling activities. These activities are discussed qualitatively in Section 5.2.

#### 5.1.3.3 Toxicity Assessment

Toxicity criteria used in this assessment are not measured precisely, like a measurement of distance, but are based on extrapolation of data from high concentrations at which an effect can be observed in humans or animals to much lower concentrations comparable to those present in the environment. To illustrate the variability in that interpretation, Table 9 presents the predicted risks for the three key chemicals contributing to inhalation risk (benzene, tetrachloroethylene, and hexavalent chromium) using the California criteria (Cal/EPA; basis for risk calculations in Attachment 5) and alternative potency measures. The risks are predicted using up to three different regulatory references for toxicity criteria: California's Environmental Protection Agency (Cal/EPA; basis for risk calculations in Attachment 5), USEPA, and NIOSH (22 CCR § 68400.5, 69020-69022, USEPA, 2020a; NIOSH, 2013). As shown in Table 9, risks estimated using Cal/EPA's toxicity criteria are approximately 4 to 20 times higher than risks using toxicity criteria from USEPA. NIOSH published an inhalation unit risk value for hexavalent chromium, and the predicted risk is approximately 5-times lower than risks predicted using Cal/EPA's toxicity criteria. It should be noted that although exposure frequency and duration are not consistent between the NIOSH unit risk estimate and our exposure scenarios, we corrected for the difference in our calculations to predict the risk estimates in Table 9.

Further, it is noteworthy that the NIOSH cancer potency estimate for hexavalent chromium was developed in 2013 using a robust data set (more than 2000 workers exposed from 1950-1980s) for whom exposures were characterized using an extensive exposure monitoring data set, and NIOSH quantitatively addressed the risk associated with smoking behavior. By comparison the California potency estimate, which was used in this evaluation, was developed in 1985, based on a very limited data set of fewer than 300 workers, exposed in the 1930s, and for which, no measures of hexavalent chromium were collected (CDHS, 1985). The NIOSH assessment is far superior technically than the highly dated assessment used in California, and it expected that the cancer risk associated with hexavalent chromium calculated using the California potency estimate is overestimated because of the dated analysis used to derive the California unit risk value. The cancer risk calculated using the NIOSH unit risk estimate is 5 in 10,000 (Table 9), and it is noteworthy that hexavalent chromium was only measurable in one sample from our study.

#### 5.1.3.4 Risk Characterization

These hypothetical risk calculations are based on estimates of both exposure and toxicity that, when combined, may compound the uncertainty in the risk estimates. As with any risk assessment, assumptions are required to quantify potential human exposure and risk. Most assumptions were conservative and overestimate potential exposure and risk. Those assumptions that potentially underestimated potential exposure and risk typically resulted in low or insignificant effects to the predictions.

It is also important to recognize the difference between calculated probabilities in the risk assessment and observed cancer incidence. The calculated risk probabilities are predictors of the likelihood of cancer based on numerous assumptions and models, many of which are designed to overestimate risk rather than underestimate it. This is not the same as identifying actual incidences of cancer in a specific population.

#### **5.2** Qualitative Discussion of Cancer Risks

This section discusses various potential exposures that could not be quantified. During sampling activities, representative concentrations could not be collected for a field-assigned fire equipment mechanic working at a wildfire base camp or a helicopter maintenance inspector at Air Operations painting/priming/sanding aircraft parts. During our visit to the Eastern Fire Shop on November 4, 2020, brake pads were observed with a Proposition 65 warning for the presence of carcinogens, but information regarding the chemical composition of the brake pads was not available for assessing potential exposure risks. Finally, some chemicals were not analyzed in the sampling effort, because regulatory toxicity criteria were not available to quantify potential risk. In the absence of those quantitative data, a qualitative discussion of potential carcinogenic risks is presented for each of these scenarios.

#### 5.2.1 Field-Assigned Fire Equipment Mechanic at a Wildfire Base Camp

As described in the Task 2 report (ToxStrategies, 2020c), the job of repairing fire apparatus or other equipment at a wildfire base camp or at a municipal fire site resulted in a "very high" risk ranking and was thus prioritized for the evaluation of cancer risk. Depending on the number of wildfires that occur each year, field mechanics may be called to a wildfire base camp for approximately 2-week durations, 24 hours per day. During these events, the mechanic wears work boots, a work uniform, gloves, eye protection, and N95 respirators. So, while this exposure may be more intense than daily work at the fire shop, it is also much less frequent (7.7% of their total year if they work for 28 days in the field per year and if they pull two shifts every fire season). There is also a great deal of variability in this potential exposure, depending on where the base camp is set up, which direction the wind is blowing, how far the base camp is from the active fire, and how many fires are contributing to air quality conditions. Given the infrequent occurrence (possibly 7.7% of a year) and shorter exposure duration (once every three years for 45 years), the potential exposures of field mechanics is not expected to be as high as exposures in the shop.

The carcinogens that were prioritized for the quantitative assessment (Task 4; ToxStrategies, 2020d) were acetaldehyde, benzene, ethylbenzene, naphthalene, diesel particulate, formaldehyde, and PAHs in air; and PAHs, chlorinated dioxins/furans, PCBs, pentachlorophenol, arsenic, and lead in surface wipes. Although the field-assigned fire equipment mechanic's exposure could not be assessed for these chemicals, Materna et al. (1992), characterized firefighters' exposures to acetaldehyde, benzene formaldehyde, and PAHs in air while working at northern California wildland fires between 1987 and 1989. These authors found that firefighter industrial hygiene samples collected during wildland firefighting demonstrated potential for low-level exposures to these carcinogens (Materna et al., 1992). As a point of comparison, benzene was sampled for at the Eastern Fire Shop

(PBZ air samples and area samples) and benzene was not detected ( $<71 \mu g/m^3$ ), while Materna et al., measured approximately 1,600  $\mu g/m^3$  at the active fire site. As such, it is recognized that exposure concentrations at active fires may exceed that which occurs at the shops, even though mechanics do not spend a significant fraction of their working lifetime at an active fire.

ToxStrategies estimates that the concentrations measured on the surface of a fire apparatus at a wildfire base camp would not likely result in risk above 1 in 10,000, based on the following rationales:

- The surface wipe samples collected at the Eastern Fire Shop on the fire apparatus that had been to a recent wildfire had detections that did not exceed the 1-in-10,000 risk level for the dermal or ingestion pathway.
- The surface wipe locations on the fire apparatus collected from the Eastern Fire Shop were areas that are not cleaned regularly and are not easily accessible; therefore, the dust that was captured on the wipe sample was an accumulation of fire residues from, presumably, several fire events (wildfires and/or municipal fires).
- The surface wipe samples collected on the aircraft that had recently been to a wildfire had detections that did not exceed the 1-in-10,000 risk level for the dermal or ingestion pathway.

#### 5.2.2 Helicopter Maintenance Inspector at Air Operations

In addition to the heavy and intermediate maintenance tasks, the helicopter maintenance inspector performs painting, priming, and sanding of aircraft components. This work can take place in the paint booth, inside the hangar, or outside in the open air, depending on the aircraft component. The carcinogenic chemicals associated with the painting tasks include methylene chloride, hexavalent chromium, 4-chlorobenzotrifluoride, and ethylbenzene. Based on discussions with the Air Operations staff, the painting work performed by the helicopter maintenance inspector typically takes place in the paint booth, and with the use of an airline respirator. The airline respirator effectively eliminates the inhalation pathway for exposure, because it supplies clean breathing air to the inspector. Although air concentrations of the chemicals could not be measured, because this activity was not conducted on the days of the exposure assessment, a supplied-air respirator, when properly fitted, has a protection factor of 1000, meaning that it reduces by 1000-fold the air concentrations of chemicals to which the wearer is exposed. Given the performance of the painting operations inside a ventilated paint booth and the use of a supplied-air respirator, the possibility for significant inhalation exposure is extremely low.

#### 5.2.3 Brake Pad Repair by a Shop-Assigned Fire Equipment Mechanic

During the quantitative exposure assessment site visit to the Eastern Fire Shop in Los Angeles on November 4, 2020, ToxStrategies observed Proposition 65 warning labels or generic "caution" labels on the packaging of some friction materials (e.g., brake pads, shoes, linings) used to maintain heavy-duty vehicles. These labels warned of potential cancer risk and/or reproductive harm. ToxStrategies subsequently requested copies of

Material Safety Data Sheets (MSDSs) or Safety Data Sheets (SDSs) for each of the friction materials. We received an MSDS for a brake lining supplied by Meritor Genuine, Product No. 292, dated January 7, 2013. This MSDS did not identify any potential for cancer risk or that the product was regulated under Proposition 65 (California Safe Drinking Water and Toxic Enforcement Act of 1986). In contrast, the packaging for other Meritor Genuine products observed during the site visit included a caution label regarding possible cancer risk. We have not received MSDSs or SDSs for the remaining friction products, nor were these documents readily available in the public domain. Accordingly, we have not included the potential cancer risk, if any, from exposure to friction material components in our evaluation. This issue could be investigated further as part of future health evaluations of fire equipment mechanics.

### 5.2.4 Chemicals Without Regulatory Toxicity Criteria

Exposure to six chemicals was not measured, because, although they have been identified as potential carcinogens, toxicity criteria were not available from the regulatory references evaluated. Specifically, diethanolamine and tetrahydrofuran are present in chemicals used for helicopter maintenance at Air Operations, and cumene, tetrabromobisphenol-A, methyl isobutyl ketone, and diethanolamine are present in chemicals used by fire equipment mechanics at the Eastern Fire Shop. Hence, theoretical excess cancer risks associated with exposure to these chemicals have not been assessed, and therefore, it is unknown what additional excess cancer risk, if any, would be posed by these chemicals.

### **6** Conclusions

A quantitative estimate of carcinogenic risk was calculated based on measurements and assumptions regarding chemicals of potential concern, exposure, and quantitative measures of carcinogenic potency. Several air and surface wipe samples were collected on a single day at each of three locations (Air Operations, the Breathing Apparatus Shop, and the Eastern Fire Shop) for the purpose of measuring exposure to chemicals from workplace exposures. Several chemicals were detected in one or more samples, which were identified as COPCs for the purpose of this evaluation. SEGs were identified in Task 2 of this project, which categorized the workers based on how they may be exposed during their workday. Exposure assumptions were developed for each SEG to quantify exposure rates. Inhalation, dermal contact, and incidental ingestion routes of exposure were evaluated for each of the SEGs.

Based on the results of the exposure and risk calculations performed herein, inhalation was identified as the exposure route that contributed most significantly to potential exposure and risk, although all measured concentrations were below PELs for all chemicals. A single chemical in air at each of the locations for each SEG was identified as contributing most significantly to risk estimates above the threshold of 1 in 10,000: hexavalent chromium at Air Operations (20 in 10,000), benzene at the Breathing Apparatus Shop (30 in 10,000), and tetrachloroethylene at the Eastern Fire Shop (400 in 10,000). Estimated risks for other SEGs and tasks were below 1 in 10,000. Data were not collected for field-assigned fire equipment mechanics and helicopter maintenance inspectors, because those activities did

not occur at the time of sampling. These SEGs are considered to have relatively low exposure potential because of the short duration and the use of personal protective equipment.

It is noteworthy that these risk estimates are based on current sampling data and are not reflective of past exposures. As worker safety and health practices typically improve with time, it is reasonable to assume that exposures in the past were higher and different than those quantified in this study.

The measured air concentrations of carcinogenic chemicals to which the helicopter mechanics, equipment maintenance workers, and fire equipment mechanics are exposed did not exceed the Cal/OSHA PELs; however, PELs are not always set to be protective of an increased cancer risk. Nevertheless, to reduce potential cancer risk, a variety of control measures consistent with the NIOSH hierarchy of controls (eliminate, substitution, engineering controls, administrative controls, and use of personal protective equipment) could be considered. Examples include:

- Eliminate tetrachloroethylene-containing products, replacing them with products that do not contain carcinogens.
- Increase ventilation in the Breathing Apparatus Shop to reduce benzene air concentrations.
- Identify work practices at Air Operations that increase the potential for airborne hexavalent chromium releases, and modify practices/procedures to reduce the exposure.

### 7 Next Steps

For Task 3, Epidemiologic Assessment, employee records are being evaluated for completeness and suitability for a future cancer epidemiology study.

Task 6 may include analyzing public comments, explaining the rationale for specific policy recommendations, and disseminating the study findings to the governor, state legislature, Occupational Safety and Health Standards Board, Los Angeles County Board of Supervisors, and stakeholders in the workers' compensation system.

## Notes

GIABS = Fraction of contaminant absorbed in gastrointestinal tract (unitless)

RBA = Relative bioavailability

\* = Bisphenol A selected as surrogate chemical for selection of GIABS

Notes

Bold font indicates maximum value used as representative concentration when fewer than five samples collected.

Regular font represents detection limits or average values for data sets with more than five detections.

 $\frac{Abbreviations}{--=data not collected} \\ \mu g/m^3 = microgram per cubic meter$ 

Table 5. Representative concentrations for exposure evaluations based on surface wipe samples (µg/cm²)

1. The analytical results for dioxins/furans and 12 PCB congeners with a toxicity equivalency factor (TEF) were converted to a 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) toxic equivalence (TEQ) concentration. Congeners that were non-detects were assigned values equal to 50% of the reporting limit for calculating the dioxin/furan/PCB TEQ totals for each sample.

2. The non-TEQ PCBs total are calculated by summing the individual congeners without a TEF. Congeners that were non-detects were assigned values equal to 50% of the reporting limit for calculating the non-

TEQ PCB totals for each sample. **Bold** font indicates maximum value used as representative concentration when fewer than five samples collected.

Regular font represents detection limits or average values for data sets with more than five detections.

Abbreviations
PCB = polychlorinated biphenyl
TEQ = toxicity equivalency

-- = data not collected

 $\mu g/cm^2 = microgram per square centimeter$ 

Table 6. Toxicity criteria for carcinogenic effects based on inhalation exposure

|              |                                              |                | EPC - Heavy     | maintenance <sup>1</sup> | 0.084         |

### **Notes**

1. For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

### **Abbreviations**

EPC = exposure point concentration  $\mu g/m^3 = micrograms$  per cubic meter **Bold** indicates detected result. Shaded represents the EPC

### Notes

Sample duration is based on an estimated sample end time of 2:30pm. The results may be biased high, but the results were non-detect.

### **Abbreviations**

 $\mu$ g/m<sup>3</sup> = micrograms per cubic meter Shaded represents the EPC

<sup>1.</sup> For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

<sup>\*</sup> Sample duration is uncertain; personal sampling air pump faulted between the times of 1:30pm and 3:15pm.

### Notes

2. The units were converted from  $mg/m^3$  to  $\mu g/m^3$ .

### **Abbreviations**

 $mg/m^3 = milligrams$  per cubic meter  $\mu g/m^3 = micrograms$  per cubic meter Shaded represents the EPC

<sup>1.</sup> For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

|          |                                                          |                      | EPC <sup>1</sup>             | 0.54    |

### Notes

1. For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

### Abbreviations

μg/cm<sup>2</sup> = micrograms per square centimeter Shaded represents the EPC

**Bold** indicates detected result.

### Notes

1. For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

### Abbreviations

 $\mu g/cm^2 = micrograms \ per \ square \ centimeter$ 

Shaded represents the EPC

PCBs = polychlorinated biphenyls TEQ = toxic equivalence

Bold indicates detected result.

- 1. For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.
- 2. The units were converted from mg/m³ to μg/m³.
- 3. Diesel particulate as elemental carbon measured in Sample EL0129 was determined to be an outlier and removed from the dataset.

### Abbreviations

EPC = exposure point concentration mg/m<sup>3</sup> = milligrams per cubic meter  $\mu g/m^3 = micrograms per cubic meter$ **Bold** indicates detected result.

### Notes

1. For data sets with more than five samples, the EPC was either (1) the average of the samples where the non-detects were treated as one-half of the detection limit, or (2) the maximum detection limit if the chemical was not detected in any sample. For data sets with fewer than five samples, the EPC was either (1) the maximum detected value, or (2) the maximum detection limit.

\* The pre- and post- flow rate was different by approximately 13%; therefore, this reporting limit is an estimate (the true reporting limit is between 0.47 and 0.55  $\mu g/m^3$ ).

# **ATTACHMENT 4**

# Dermal Absorption Factors

### **Attachment 4**

## **Dermal Absorption Factors**

Summaries of the scientific studies used to derive the dermal absorption percentages are presented below.

## Arsenic

A value of 6% was used as the percent of arsenic absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the results of a study by Wester et al. (1993a).

Wester et al. (1993a) studied the *in vivo* percutaneous absorption of radiolabeled soluble arsenic (as  $H_3^{73}AsO_4$ ) from soil (180–300 µm). Doses of 0.00004 and 0.6 µg/cm² arsenic skin concentration were dermally applied to the abdomens of female rhesus monkeys (n=3 or 4 per dose group) in soil loadings of 40 mg soil/cm² for 24 hours. Urine samples were collected during the exposure period and for the subsequent six days. Percutaneous absorption was estimated as the ratio of urinary excretion following exposure to intravenous administration, the latter of which was radiolabeled <sup>73</sup>As in water administered in four monkeys. Percutaneous absorption for the low and high doses was reported to be  $4.5\pm3.2\%$  and  $3.2\pm0.9\%$ , respectively.

OEHHA noted several limitations to the Wester et al. (1993a) study that may have led to an underestimation of absorption, including (1) the large soil particle fraction used in the study compared to a particle size typically used in soil dermal absorption studies [<150 µm], (2) not investigating the mass of arsenic retained in the skin, and (3) the uncertainty of whether the soil remained in contact with the skin throughout the entire exposure period.

OEHHA averaged the low- and high-dose percutaneous absorption percentages (3.9%) from Wester et al. (1993a) and applied a factor of 1.63 to account for the increase in absorption potential from soil particles <150  $\mu$ m compared to the larger particles used in the study, based on evidence from Nico et al. (2006). The percutaneous absorption percentage was rounded to the nearest whole number (3.9% × 1.63 = 6.4% = 6%).

# Benzo(a)pyrene and PAHs

A value of 13% was used as the percent of PAHs as benzo[a]pyrene (BaP) absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the results of a study by Wester et al. (1990).

D- 1

Wester et al. (1990) evaluated the *in vivo* dermal uptake of BaP in rhesus monkeys (n = 4). Soil (180–320  $\mu$ m) containing 10 ppm BaP was loaded (40 mg/cm²) to abdominal skin with a non-occluded protector for 24 hours. Urine was collected throughout the exposure period and for the six days following exposure. The dermal absorption percentage, corrected by taking into account absorption among a group of monkeys with intravenously administered BaP, was  $13.2\pm3.4\%$ .

OEHHA adopted an absorption factor of 13%, given that Wester et al. (1990) was an *in vivo* animal study and considered mass balance with the intravenous group. This adoption was supported with a study by Moody et al. (2007) that found a dermal absorption of 14.8% following human *in vitro* dermal exposure for 24 hours.

### Hexavalent chromium

A value of 2% was used as the percent of hexavalent chromium absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the results of a study by Czernielewski et al. (1965).

Czernielewski et al. (1965) evaluated the whole-body absorption of radiolabeled hexavalent chromium (as  $Cr^{51}$ ) dermally applied to guinea pigs (n = 9) for 24 hours. One dose of a sodium chromate solution (15 µg in 0.1 mL) was applied to a 4-cm<sup>2</sup> shaved area. Following the exposure period, samples were taken from urine, feces, blood, heart, liver, spleen, adrenals, kidneys, lungs, lymphatics, and skin. A total absorbed dose of 2.9% was estimated, of which 1.6% was in blood, 1.1% in excreta, and 0.2% in the remaining organs and tissues.

To estimate an absorption factor associated with a soil vehicle, OEHHA applied a factor of 0.83, based on the maximum bioaccessibility of hexavalent chromium in synthetic sweat (Wainman et al., 1994). The soil vehicle absorption was rounded to the nearest whole number  $(2.9\% \times 0.83 = 2.41\% = 2\%)$ .

### Lead

A value of 3% was used as the percent of lead absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the results of a study by Filon et al., 2006.

Filon et al. (2006) assessed the *in vitro* absorption of lead oxide (PbO) powder (<10  $\mu$ m) in human abdominal skin via diffusion cells 3.14 cm² in area (5 mg PbO/cm² and 2 mL synthetic sweat at pH 5.0). Following 24 hours, authors reported 0.06% fractional absorption into the skin and 6.4% (median) fractional absorption into the skin after surface decontamination. When PbO was removed with soap after 30 minutes, the mass of lead

absorbed over 24 hours was not reduced, suggesting that lead is absorbed rapidly through human skin.

OEHHA assumed that the fraction of lead absorbed in the skin was available for systemic absorption and applied a factor of 0.41 to correct for lead solubility in soil based on a study of heavily contaminated soil with a pH of 5.0 (Zhang et al., 1998). The absorption factor was rounded to the nearest whole number  $(6.4\% \times 0.41 = 2.6\% = 3\%)$ .

# Naphthalene

A value of 1.17% was used as the percent of naphthalene absorbed through the skin. This value is based on the results of a study by Riviere et al. (1999).

Riviere et al. (1999) used radiolabeled  $^{14}$ C-naphthalene in an *in vitro* porcine skin flaps study measuring percutaneous absorption and cutaneous disposition of jet fuels. Naphthalene is a primary aromatic constituent of jet fuel at 1.1%, and the addition of radiolabeled  $^{14}$ C-naphthalene as a marker compound only marginally increased the total naphthalene concentration to 1.21%. Researchers applied three formulations (Jet-A, JP-8, and JP-8(100)), in doses of 25  $\mu$ L of jet fuel containing 2  $\mu$ Ci of  $^{14}$ C-naphthalene, directly to the skin flap and then monitored the absorption, penetration, and distribution. Perfusate samples (3 mL) were collected every 5 minutes for the first 40 minutes, then every 10 minutes until 1.5 hours, and then every 15 minutes until termination at 5 hours. Naphthalene showed peak absorption at less than one hour, with a mean percent dose absorbed of 1.17 (n = 4) in one formulation. This study showed evidence that naphthalene is absorbed and has a minimal propensity to remain in the skin, although it tends to partition into subcutaneous fat after absorption.

# Pentachlorophenol

A value of 25% was used as the percent of pentachlorophenol (PCP) absorbed through the skin. This value is based on the USEPA Regional Screening Levels (USEPA, 2020) and USEPA Supplemental Guidance for Dermal Risk Assessment (USEPA, 2004). USEPA derived this value from the results of a study by Wester et al. (1993c).

Wester et al. (1993c) evaluated the *in vivo* percutaneous absorption of radiolabeled PCP ( $^{14}$ C) in soil. Soil containing 0.7 µg PCP/cm² was loaded to a 12-cm² abdominal area on rhesus monkeys (n = 4) for 24 hours. The abdominal area was protected by a non-occluded cover. Urine was collected during the exposure period and for the subsequent six days. Percutaneous absorption was estimated as the ratio of urinary excretion following exposure to intravenous administration, the latter of which was radiolabeled  $^{14}$ C administered in four monkeys. A resulting percutaneous absorption of PCP from a soil vehicle was estimated to be 24.4±6.4% following a 24-hour exposure. An average of 38% PCP was recovered in the test chamber, residue, and surface washes. USEPA adopted 25% as the PCP absorption factor from soil.

## PCBs (Total)

A value of 14% was used as the percent of total PCBs absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the results of a study by Wester et al. (1993b).

Wester et al. (1993b) evaluated the *in vivo* dermal uptake of Aroclor 1242 (68% tri- and tetra- congeners) and Aroclor 1254 (83% penta- and hexa- congeners) in female rhesus monkeys (n = 4). Soils containing 44 ppm Aroclor 1242 and 23 ppm Aroclor 1254 were applied to a 12 cm² area of abdominal skin with a non-occluded patch for 24 hours. Soil loads were 40 mg/cm². After 24 hours of exposure, systemic absorption was measured through urine and feces samples, with samples being collected for an additional 34 days after the exposure period. Corrected dermal absorption percentages, taking into account absorption among a group of monkeys with intravenously administered PCBs, were 13.9% and 14.1% for Aroclor 1242 and Aroclor 1254, respectively. Authors compared their results to an *in vitro* assay using human skin, and the amount of absorption was found to vary by dosing vehicle, with partition coefficients of 13.8 and 14.1 for Aroclor 1242 and Aroclor 1254, respectively, when administered in soil.

OEHHA adopted an absorption factor of 14%, given that the Wester et al. (1993b) was an *in vivo* animal study and considered mass balance with the intravenous group.

# 2,3,7,8-Tetrachlorodibenzo-p-dioxin

A value of 3% was used as the percent of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) absorbed through the skin. This value is based on the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix F (OEHHA, 2012). OEHHA derived this value from the analysis and results of studies by USEPA (1992) and Roy et al. (2008).

USEPA (1992) and Roy et al. (2008) studied the absorption of TCDD from low organic soils (LOS) in rats *in vitro*, human *in vitro*, and rats *in vivo*. Exposures occurred in intervals for up to 96 hours. The LOS contained 1 ppm TCDD, and the soil loading on rat and human skin was 10 and 6 mg/cm², respectively. Following 24-hours, the percent of TCDD absorbed by rat skin *in vitro* was 1.17%, by human skin *in vitro* was 0.28%, and by rats *in vivo* was 7.9%. Steady-state dermal absorption was achieved after 24 hours in the *in vitro* studies; therefore, it was expected that the dose in the skin sample at 96 hours, after wiping, may be added to the percent absorbed after 24 hours to estimate a total percent absorbed. The percent in the skin sample at 96 hours, after wiping, was 1.4% in rats *in vitro* and 0.2% in human *in vitro*.

To estimate a 24-hour percent absorption in humans, OEHHA multiplied the 24-hour rat *in vivo* percent absorption by the ratio of the total percent absorbed in humans *in vitro* to absorbed in rats *in vitro*. This results in a human absorption percentage of 1.4% ( $7.9\% \times [0.48\% / 2.75\%] = 1.4\%$ ). To account for the difference of soil loading in the human *in* 

vitro study (6 mg/cm<sup>2</sup>) and a monolayer loading (3 mg/cm<sup>2</sup>), OEHHA included a factor of 2 in the absorption derivation. The absorption factor was rounded to the nearest whole number  $(1.4\% \times 2 = 2.8\% = 3\%)$ .

- Notes:

  1. These calculation based on maximum detected concentration in air (Ca).

  2. These values on maximum detected concentration in air (Ca).

  3. Nor inhalition unit risk (UR) for expression of desel particulate as elemental carbon but it was determined to be an outlier and removed from the dataset. Therefore, the risk calculation is based on the detection limit (see screening risk calculation or in risk (UR) for expression and risk via inhalition exposure could not be calculated. However, all samples were non-detect.

  4. Sercentral size skellarismum detection limit (see screening risk calculation based on maximum detection limit (see screening risk calculation).

  5. ToxStrategies derived the IUR for styrene using OEHHA. 2010 and Cruzan et al., 2001.

Notes

1. Risk calculation based on representative concentration on surface wipe (Csw).

2. Screening risk eductation based on maximum detection limit.

Abheroinium
COPC – denoise of potential conterm
GARS – fraction of contaminant absorbed in gestrointestinal tract (unitless)
GARS – fraction of contaminant absorbed in gestrointestinal tract (unitless)
GARS – fraction of contaminant absorbed in gestrointestinal tract (unitless)
As – in organizable chemical described, so screening risk calculations were performed using the detected concentration
PCB – probybdremated biphory!
SFO – oral slope factor
TEQ – oxet equivalence
Jugoria – oxet equivalence
Jugoria – oxet equivalence
Magnatic – per (unifigrams per kilogram-day)
(mg/eg-day)\* – per (unifigrams per kilogram-day)
(mg/eg-day)\* – per (unifigrams per kilogram-day)
— e-bernical not measured.

Chemical of potential concern (COPC) not measured and not relevant to this location.

# Attachment 5-C. Risk calculations for ingestion exposures

# Risk calculations based on detected concentrations of chemicals of potential concern (COPCs)<sup>1</sup>

Note:

1. Risk calculation based on maximum detected concentration on surface wipe (Csw).

2. The USEPA recommends a default value of 60% for relative bisavailability (RBA) of arsenic and load in soil (U.S. EPA, 2021a and 2021b). All other COPCs have a default RBA of 100%.

3. Sereening risk calculation based on maximum detection limit.

Abbreviations

COPC – chemical of potential concern

RAA = chemical of potential concern

RAA = chemical obtained (%)

NA = roun opplicable; chemical detected, so screening risk calculations were performed using the detected concentration.

PCB = polychlorunaid detected, so screening risk calculations were performed using the detected concentration.

PCB = polychlorunaid detected, so screening risk calculations were performed using the detected concentration.

PCB = polychlorunaid expensions per square continuetes

of present (with expensions) = per (milligames per kinggmm-day)

my up, a milligame per micrograms

- exhorminal not measured

Chemical of potential concern (COPC) not measured and not relevant to this location.

Red shading indicates risks greater than 1 in 10,000 (TE-04)
