Specialty Society and Society Representative Listing:
ACOEM acknowledges the following organizations and their representatives who served as reviewers of the Occupational/Work-related Asthma Guideline. Their contributions are greatly appreciated. By listing the following individuals or organizations, it does not infer that these individuals or organizations support or endorse the Occupational/Work-related Asthma Guideline developed by ACOEM.

American College of Chest Physicians
Diego J. Maselli, MD, FCCP

American Thoracic Society
Lisa Maier, MD, MSPH, FCCP

Other External Reviewers:
Theodore Lytras, MD, MPH
Mary C. Townsend, DrPH

These panel members represent expertise in occupational medicine, internal medicine, preventive medicine, pulmonary medicine, allergy and immunology, toxicology, aerospace medicine, and epidemiology. As required for quality guidelines (Institute of Medicine’s (IOM) Standards for Developing Trustworthy Clinical Practice Guidelines and Appraisal of Guidelines for Research and Evaluation (AGREE)), a detailed application process captured conflicts of interest.

IMPACT
Asthma is a common chronic disorder of the airways that involves a complex interaction of airflow obstruction, bronchial hyperresponsiveness, and underlying inflammation. Increased airway responsiveness to a variety of stimuli is typical. Work-related asthma (WRA) includes both occupational asthma (OA, asthma of occupational origin) and work exacerbated asthma (WEA). OA includes sensitizer-induced asthma, resulting from sensitization to an antigen in the workplace, and irritant-induced asthma, resulting from reactive airways disease, which has been provoked by workplace exposures to irritants. Each has the potential for considerable acute morbidity, long-term disability, and adverse social and economic impacts.

Occupational asthma has become the most common form of occupational lung disease in many industrialized countries, with approximately 10 to 15% of all prevalent cases of adult asthma attributed to occupational factors. The percentage of new onset adult asthma attributable to occupational causes is considered to be much higher, up to a third of all cases. The frequency of work-exacerbated asthma, defined as preexisting reactive airways disease that is made temporarily or permanently worse due to occupational exposures, is known to be much higher than new-onset occupational asthma.

The diagnosis of occupational asthma is a specialty-level function and is usually done by physicians who have special training and expertise in occupational lung disease and workplace exposures. If the treating physician does not have this specialized expertise, prompt referral is advised.

WORK-RELATED ASTHMA
Work-related asthma (WRA) presents with symptoms of asthma that began or became worse at work, usually in the context of exposure to a new chemical or environmental change. The symptoms may occur during or after work hours. The specific respiratory symptoms in WRA patients are the same as in non-WRA patients, which requires a high level of suspicion and incorporation of work history in the evaluation of all cases of adult-onset asthma. They include cough, wheeze, shortness of breath, and chest tightness, with physiological evidence of reversible/variable airway obstruction and/or hyperresponsiveness.

Occupational asthma (OA) is defined as new onset asthma in the workplace and can be caused by exposure to either a workplace sensitizer or an irritant. OA is further classified into OA with latency or OA without latency. OA without latency is less common and is believed to represent between 5 and 15 percent of all OA cases. OA with latency is observed in all instances of immunologically mediated asthma. The latency period, which represents the time between the first exposure and the development of symptoms, can vary from weeks to years. It reflects the time for induction of an immunological response to the workplace allergen. OA without latency can occur after a single exposure to irritant gas, fumes, or chemicals, such as nitrogen oxide, ammonia, and chloride. This was originally classified as reactive airways dysfunction syndrome (RADS). RADS is an overused diagnosis and often confused with irritant-induced occupational asthma and WEA. RADS should be reserved for new onset reactive airways associated with a single incident. It classically relies on a single high-level (non-routine) exposure to an inhaled irritant.

Brooks and other authors have suggested modification of these criteria to include a role for multiple cumulative irritant insults or even for an allergic diathesis along with the irritant exposure that would result in new onset workplace asthma that would involve latency. It has been reported that low-level irritant-induced occupational asthma with latency is clinically indistinguishable from sensitization-induced asthma. However, clear-cut guidelines beyond Brooks 1985 have not been established for such irritant induced asthma. WEA is the activation of preexistent asthma or bronchia hyper-responsiveness by many factors such as temperature, exercise, dust, or low level irritants.
Prevalence estimates of asthma and WRA have been assessed in small cohort and cross-sectional studies. Studies of workplaces with exposures to specific substances reported prevalences of asthma or OA ranging from 3% to 54%.(1, 2, 23, 24) More than 200 agents have been reported to cause WRA, based on epidemiological and/or clinic evidence. Asthmagens (sensitizing antigens resulting in asthma) are often classified into categories based on their molecular weight, with high molecular weight defined as >5,000 daltons versus low molecular weight <5,000 daltons. Molecular weights are believed to be important in the mechanisms of action in the development of OA.(1)

The predisposing factors for developing WRA are not well known. Atopy is the primary established risk factor for occupational asthma, operating largely with respect to high molecular weight antigens such as animal proteins. It has been proposed that human leukocyte antigen class-2 (HLA class II) alleles can be a risk factor for the development of WRA resulting from low-molecular weight agents.(12, 25, 26) However, HLA typing is not routinely performed for asthma clinically and has no demonstrated value in individual diagnosis.

Medical management and compensation decisions require a thorough assessment of suspected OA. OA may be mistaken for non-occupational asthma unless a detailed history, including occupational history, and appropriate medical tests are performed to support an association with work.(27)

**SUMMARY OF RECOMMENDATIONS**

**Summary Table: Recommendations and Evidence**

Table 1 summarizes the recommendations from the Evidence-based Practice Asthma Panel for diagnostic testing for occupational asthma. Table 2 summarizes the recommendations for management of occupational asthma. The recommendations are based on critically appraised higher quality research evidence and on expert consensus observing First Principles when higher quality evidence was unavailable or inconsistent. The reader is cautioned to utilize the more detailed indications, specific appropriate diagnoses, temporal sequencing, prior testing or treatment, and contraindications that are elaborated in more detail for each test or treatment in the body of this Guideline in using these recommendations in clinical practice or medical management. These recommendations are not simple “yes/no” criteria, and the evidence supporting them is in nearly all circumstances developed from typical patients, not unusual situations or exceptions.

Recommendations are made under the following categories:

- Strongly Recommended, “A” Level
- Moderately Recommended, “B” Level
- Recommended, “C” Level
- Insufficient-Recommended (Consensus-based), “I” Level
- Insufficient-No Recommendation (Consensus-based), “I” Level
- Insufficient-Not Recommended (Consensus-based), “I” Level
- Not Recommended, “C” Level
- Moderately Not Recommended, “B” Level
- Strongly Not Recommended, “A” Level

**Table 1. Summary of Recommendations for Diagnostic Testing for Occupational Asthma**

<table>
<thead>
<tr>
<th>TEST</th>
<th>RECOMMENDATION(S)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Spirometry</td>
<td>Spirometry testing is an essential component in the evaluation and management of patients with possible work-related asthma.</td>
</tr>
<tr>
<td>Peak Expiratory Flow Rates</td>
<td>Serial peak expiratory flow measurements as an initial evaluation method for diagnosing work-related asthma, in patients already diagnosed with asthma by other methods – Moderately Recommended, Evidence (B)</td>
</tr>
<tr>
<td>Nonspecific Bronchial Provocation</td>
<td>Nonspecific bronchial provocation test (e.g., methacholine) for use in diagnosing asthma, if the clinical history is compelling, and other tests (spirometry and bronchodilator responsiveness) are unhelpful – Strongly Recommended, Evidence (A)</td>
</tr>
</tbody>
</table>
Test | Nonspecific bronchial provocation test (e.g., methacholine) for use in diagnosing work-related asthma, as other steps are required to establish the work-relatedness of the asthma – Moderately Recommended, Evidence (B)  
Mannitol bronchial provocation test for use in diagnosing work-related asthma, and other steps are required to establish the work-relatedness of the asthma – Recommended, Evidence (C)

Specific Immunological Testing | Specific immunological testing (IgE) for workers with symptoms consistent with occupational asthma to certain high molecular weight specific allergens and when standardized antigens and assay protocols exist – Strongly Recommended, Evidence (A)  
Specific immunological testing (IgG) as a diagnostic tool for select workers with symptoms consistent with occupational asthma to high molecular weight specific allergens – Not Recommended, Evidence (C)  
Specific immunological testing (IgE) for workers with symptoms consistent with occupational asthma to low molecular weight specific allergens due to low sensitivity and specificity and lack of method validation – Not Recommended, Insufficient Evidence (I)

Skin Prick Testing | Skin prick testing for high molecular weight allergens for select workers with symptoms consistent with occupational asthma to specific allergens and where validated, commercial skin testing extracts are available – Strongly Recommended, Evidence (A)  
Skin prick testing for low molecular weight allergens for select workers with symptoms consistent with occupational asthma to specific allergens, and where skin testing extracts are available – Moderately Recommended, Evidence (B)  
Skin prick testing for allergens not covered above – Not Recommended, Insufficient Evidence (I)

Specific Inhalation Challenge Testing | Specific inhalation challenge testing for use in diagnosing work-related asthma with latency for highly select cases, where the diagnosis of occupational asthma is highly suspected, but has not been established by less invasive means – Recommended, Evidence (C)

Nitric Oxide | Nitric oxide testing for the diagnosis of occupational asthma, as it cannot differentiate between, e.g., occupational asthma and other eosinophilic lung inflammatory conditions – Not Recommended, Insufficient Evidence (I)  
Exhaled nitric oxide testing for establishing a diagnosis of asthma when more objective evidence is needed such as in litigated cases – Recommended, Evidence (C)  
Exhaled nitric oxide testing for selective use in monitoring airway inflammation in patients with moderate and severe asthma – Moderately Recommended, Evidence (B)

Nasal Lavage | Nasal lavage fluid analysis after challenge with the allergen for the diagnosis of occupational asthma – Not Recommended, Insufficient Evidence (I)  
Nasal lavage for select workers with symptoms consistent with occupational airways allergy to specific allergens – Recommended, Evidence (C)

recovery from asthma (I)

For irritant-induced asthma, exposure reduction to the lowest levels possible and careful medical monitoring should be performed to ensure early identification of worsening asthma (I).

Pharmacological treatment of work-related asthma follows general recommendations for asthma (C). Current American Thoracic Society/European Respiratory Society (ATS/ERS) recommendations for treatment of severe asthma should be followed.

Immunotherapy may be considered in settings where occupational asthma due to a specific high molecular weight (HMW) allergen has been established, when only one or a few allergens have been linked clinically to disease, when there is a standardized commercial allergen extract available for treatment, good control with pharmacotherapy cannot be established and the causative agent cannot be completely avoided for economic, professional or other reasons (I).

In the management of sensitizer-induced asthma, as available evidence indicates that most asthma will worsen in continued exposure. (I) However, it is recognized that some workers will insist on remaining in their jobs for social, economic, and professional reasons, despite counseling on the adverse health consequences. Continued exposure, even at low levels, may result in worsening asthma. If such patients remain in exposure, documentation of the recommendation regarding removal is RECOMMENDED (I). Required close and careful medical monitoring of such patients is RECOMMENDED (I) in order to ensure early identification of worsening asthma. Reducing exposure to the causal agent in addition to providing immunotherapy and other asthma management, where applicable, may be RECOMMENDED (I), and will depend on the asthmagen, level of exposure, severity of asthma (see Table 5), and the clinical judgment of the physician.

Use of respiratory protective devices as a safe approach for managing asthma, especially in the long-term and in patients with severe asthma (I).

Anti-asthma medications as a reasonable alternative to environmental interventions such as exposure reduction or medical removal. (I)

### CLASSIFICATION OF WORK-RELATED ASTHMA

#### WORK-RELATED ASTHMA

Occupational/work-related asthma may be classified as follows:

1. Exacerbation of pre-existing asthma (WEA)
   a. Irritant Gases
   b. Allergens
   c. Other (e.g., environmental tobacco smoke, exercise, other irritants)

2. New Onset Asthma
   a. Without sensitization
      i. Endotoxin (Byssinosis from cotton dust)\(^1\)
      ii. Cholinesterase inhibitors (pesticide exposure)
      iii. Inflammatory response (chlorine, ammonia)
      iv. Irritant induced:
         1. Acute irritant exposure (RADS)
         2. Low level irritant exposure with latency\(^2\)
         3. Cold –induced (non-specific)
         4. (Non-specific)
   b. With sensitization
      i. High molecular weight compounds – IgE mediated (complete allergens: animal, plant, bacterial)

---

\(^1\)In the early stage when there is reversible airflow constriction and before it becomes a fixed obstruction.

\(^2\)New onset asthma due to low level irritant exposure has been described but is not widely accepted in the absence of pre-existing airway hyperreactivity.
ii. Low-molecular weight compounds
   1. IgE-mediated (platinum, antibiotics)
   2. Uncertain mechanism (isocyanates, amines, acid anhydrides, plicatic acid)

<table>
<thead>
<tr>
<th>Nomenclature</th>
<th>Term</th>
<th>Defining Features</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sensitizer-induced occupational asthma (OA)</td>
<td>Occupational asthma with latency of allergic or presumed immunological mechanism (not necessarily IgE)</td>
<td>Immunological/hypersensitivity component and diagnostic tests include measures of specific sensitization (e.g. skin prick test, serum specific IgE, circulating IgC against the antigen or skin sensitization).</td>
</tr>
<tr>
<td>Irritant-induced occupational asthma (OA)</td>
<td>Occupational asthma without latency</td>
<td>No allergic component and worker is not “sensitized” to an agent; rather, the agent causes inflammatory responses through irritant mechanisms.</td>
</tr>
<tr>
<td>Work-exacerbated or work-aggravated asthma (WEA)</td>
<td>Work-exacerbated or aggravated asthma (no latency period)</td>
<td>Worker has prior or concurrent history of asthma not induced by that workplace. The worker is not sensitized to an agent at work, but is irritated by a “non-massive” exposure (e.g. cold, exercise, non-sensitizing dust, fumes, or sprays) that provokes an asthmatic reaction.</td>
</tr>
</tbody>
</table>

Adapted from the American College of Chest Physicians (ACCP).

There are many occupations and exposures that have been associated with allergic occupational asthma. A list of common occupations and exposures is provided in Malo & Chan-Yeung 2009 (available at: http://www.jacionline.org/article/S0091-6749(08)01671-0/pdf).

ETIOLOGY

More than 300 natural and synthetic chemicals have been implicated in causing WRA. This section highlights a few commonly encountered chemicals causing “asthma with latency” (a term that suggests a process that does not provoke a response on first contact, which implies that sensitization may be the mechanism) that are seen in the occupational setting. More extensive lists of agents and occupations are available (e.g., “Agents Causing Occupational Asthma with Latency” in Malo & Chan-Yeung 2009: http://www.jacionline.org/article/S0091-6749(08)01671-0/pdf; Toxnet: http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?HSDB; Centers for Disease Control and Prevention: http://www.cdc.gov/niosh//topics/; Agency for Toxic Substances and Disease Registry: http://www.atsdr.cdc.gov/; and Haz-Map: http://hazmap.nlm.nih.gov/index.php).

When referring to etiologic chemicals, these substances are often divided between high molecular weight (HMW) and low molecular weight (LMW) agents. The former include proteins and polysaccharides of plant or animal origin (>5-10 kD) while the latter are low-molecular-weight chemicals (e.g., isocyanates, trimellitic anhydride, formaldehyde). This distinction is utilized to draw attention to typical mechanisms of pathogenesis. In particular, HMW agents can serve as a direct sensitizing antigen, leading to classic IgE mediated immune response. LMW compounds act as haptons, binding to existing proteins in the body and producing an IgE response. These mechanisms lead to asthma after a latency period. Typical HMW IgE mediated examples would be flour or laboratory animal proteins, while acid anhydrides and metals would be LMW examples.

However, there are LMW antigens that cause asthma without an IgE mechanism being currently identified. Immune mediation is thought to exist as the patients still present with a latency period. Examples include the di-isocyanates – toluene diisocyanate (TDI), methylene diphenyl diisocyanate (MDI) – and formaldehyde and cleaning agents. Even with immunologic mechanisms present, there may be
non-immune pathways operating. This has been seen with TDI as well as Western Red Cedar due to the latter containing plicatic acid.

**Specific HMW Chemicals:**
- Grains and flours, in particular wheat and soya, have been among the most commonly described products. This is due not only to the flour product itself, but at times due to bug infestation into the material as well as additives including enzymes. Bakers and food processors would be a risk group, as well as dock workers exposed to shipping of the materials.
- Animal proteins are a HMW asthma precipitant that comes from the dander, fur, hair, saliva or urine. Animal urine protein is probably the most potent immunizing source in this group. Workers at risk for this would include farmers, veterinarians, and laboratory researchers or their assistants.
- Much attention has focused on the HMW latex exposure. This natural product (derived from the rubber tree) not only causes WRA, but also contact dermatitis. This latter condition is seen most commonly in health care workers. Environmental control in the form of avoiding latex gloves has helped diminish the burden of this condition.

**Specific LMW Dhemicals:**
- Acid anhydrides are a large group of LMW compounds including phthalic anhydride, trimellitic anhydride, maleic anhydride and tetrachlorophthalic anhydride. Products manufactured include plastics, dyes, adhesives and resins, with workers involved in production as being at risk for WRA. Exposed workers with a history of cigarette use are at particular risk.
- Platinum salts and aluminum can produce symptoms in workers exposed in jewelry and alloy production. Exposed workers with a history of cigarettes are at particular risk.
- Di-isocyanates have been identified as the most common cause of LMW WRA. The commonly used di-isocyanates in industries are TDI, MDI, hexamethylene di-isocyanate (HDI), and prepolymers of MDI and HDI. They all have in common N=C=O groups that are highly reactive and explain their sensitizing properties. The reported prevalence of di-isocyanate induced asthma has varied but may have been reduced in recent years due to better preventive measures. These chemicals have properties to form polymers giving rise to polyurethane. They are used across a wide variety of industries in the production of flexible and rigid foam, binders, coatings, elastomers, and paints.

**OTHER AIRWAYS ASSOCIATED DYSFUNCTION DISORDERS**
While asthma is the principal occupational airways disorder in working adults, other conditions should be considered as part of the differential diagnosis. These may include fixed airway obstruction, upper airway abnormalities, laryngeal disorders and cardiac diseases.

These specific respiratory disorders should be considered in the differential diagnosis:
- Asthmatic bronchitis. This is an inflammatory disorder of airways that can have a hypersensitivity or an irritant component or both; bronchiectasis may also be present.
- Hypersensitivity pneumonitis. Predominantly an interstitial disease, HP often has an airways component, especially acutely.
- Chronic obstructive pulmonary disease (COPD). This disorder is characterized by a fixed obstruction to airflow with or without a reversible component. It may be associated with smoking, and manifested by emphysema or bronchitis, or dust (such as silica, coal, or asbestos) exposure.
- Allergic rhinitis and atopy. Persons with allergies often experience wheezing and reversible airflow obstruction during exacerbations of their allergies as a secondary symptom, especially during acute allergic reactions and respiratory tract infections.
• Bronchiolitis and other obstructive airways diseases in adults, such as constrictive bronchiolitis and during progression to bronchiolitis obliterans.
• Eosinophilic pneumonias. A family of disorders presenting as asthma but characterized by a hyperimmune response involving eosinophils. This family includes allergic bronchopulmonary aspergillosis (ABPA) and Loeffler’s disease.
• Upper airway obstruction in adults may be confused with asthma and stridor may be confused with wheezing. Acute upper airway obstruction, such as that occurring with epiglottitis and anaphylaxis, is a medical emergency and is unlikely to be confused with asthma. Chronic partial upper airway obstruction may be seen in tumors, sarcoidosis, vocal cord paralysis, vocal cord papilloma and a variety of rare conditions (such as retropharyngeal abscess) unlikely to be confusing in practice.(31)

DIAGNOSIS OF WORK-RELATED ASTHMA

SYMPTOMS AND SIGNS IN WORK-RELATED ASTHMA
Asthma is primarily a disease of airway inflammation and reactivity. The cardinal symptoms of asthma are episodic shortness of breath, wheezing, and cough, compared to the predominant symptoms of bronchitis that are cough and sputum production.(32)

Cough requires special attention. It has been found to be the single most troublesome complaint for patients with stable, chronic asthma, which may also be true for other airway conditions.(33) Many cases of asthma do not show wheezing and have cough as the predominant symptom(34) as do most cases of bronchiolitis.

COMPLICATIONS AND COMORBID CONDITIONS RELEVANT TO WORK
People with asthma often experience complicating conditions and symptoms that are not primary parts of the diagnosis and are usually not the endpoints for treatment but affect daily life and work. These conditions and symptoms may occur in the context of work-related asthma and may therefore, be considered to be additional outcomes arising from directly work. They are also common conditions accompanying asthma that are not work-related that affect fitness for duty and that may occur with work capacity and job performance.(35) These complicating symptoms do not necessarily change with improvement in asthma status or with treatment. These complications may affect speech and voice, alertness and cognitive acuity, and risk for sleep apnea and should be considered in assessing fitness for duty and in impairment evaluation.

• Coughing spells. These may be disruptive in the workplace and are sometimes associated with acute rhinitis and susceptibility to fragrances and capsaicin.
• Voice changes and unreliability. There are many reasons why asthma affects the voice: breathlessness, vocal cord edema due to inhaled corticosteroids, concurrent allergies, and “paradoxical vocal fold motion dysfunction” (VCD). VCD also occurs in other respiratory conditions, but is more common in asthma.(36-38) Patients with asthma and similar airway problems may have difficulty in any job requiring them to use their voice to communicate.
• Irritability, loss of concentration and restlessness. This may be due to distraction, given that cough, mild choking sensations, and breathing issues interfere with close concentration and fine work.
• Musculoskeletal symptoms. Chronic coughing and altered trunk mechanics may be associated with chest (thoracic cage) pain and low back pain.
• Leg pain. Some asthma medications (including formoterol – Foradil®) may cause restless leg syndrome, or alter tissue levels of potassium, magnesium and other elements that can cause muscle cramps.
• **Eye problems.** Abnormalities in the stability of tear film may accompany nasal inflammation and airways disorders. Cough and increased intrathoracic pressure may raise pressure levels in the eye, causing small blood vessels to become engorged and even to break.

• **Sleep disorders, fatigue, and cognitive deficits.** These connected conditions are associated with night-time asthma and disturbed sleep patterns, not just time awake at night due to wheezing, shortness of breath, leg pain, and, especially, cough. The result is a substantial decrease in performance in any task requiring mental processing, short-term memory, and sustained attention, even when asthma is treated. There has long been strong evidence that RADS also affects the upper airway. It may occur as obstructive sleep apnea because of dysfunction of the upper airway – a feature of Reactive Upper-Airways Dysfunction Syndrome (RUDS) – or it may reflect reactive airways and cough during the night. The relationship between obstructive and central (brain-driven) sleep apnea appears to be closer than has been previously believed and predominantly central apnea may account for some cases. Further, sleep apnea itself, apart from obesity, with which it is confounded, substantially raises the risk of a variety of serious complications, including heart attacks and stroke.

• **Depression.** This is common to all chronic diseases and is known to occur in asthma. Sleep deprivation may aggravate it in asthma and bronchitis.

• **Gastro-esophageal reflux disease (GERD).** GERD often coexists with asthma and may be associated with it, although both diseases are also common alone. GERD, phlegm-producing cough, and a heightened cough reflex may predispose the patient with asthma to choking and gagging.

These symptoms and signs cluster in five sets of related conditions, which have been given broad rubrics of **panic-fear, airways obstruction, hyperventilation, fatigue, and irritability.** Within these categories, symptoms and signs tend to track one another; that is, within a cluster, symptoms have been observed to appear together rather than separately.

**DIAGNOSTIC ASSESSMENT OF OCCUPATIONAL ASTHMA**

In this guideline, we emphasize pulmonary evidence-based evaluations. See MTUS General Approach to Initial Assessment and Documentation for an overview of occupational evaluations, including the history and physical examination. More specialized pulmonary history and diagnostic history is required for a diagnosis of occupational asthma. The American College of Chest Physicians published the following criteria in 1995 for establishing a diagnosis of WRA, all of which are required:

• a history compatible with occupational asthma;
• presence of airflow limitation and its reversibility;
• in the absences of airflow limitation, the presence of nonspecific airway hyperresponsiveness; and
• demonstration of work-relatedness of asthma by objective means.

The algorithm below is a consensus-based recommendation from the Evidence-based Practice Asthma Panel for the diagnostic evaluation of an individual with suspected occupational asthma.
**Algorithm 1 – Diagnostic Evaluation of Occupational Asthma with Continuing Exposure**

1. **Symptoms consistent with asthma:** wheezing, cough, shortness of breath, chest tightness or congestion.
   - Yes
   - No

2. **Medical/occupational history consistent with work-related asthma (WRA)/occupational asthma (OA)** (e.g., frequency/intensity/duration of exposures that are often associated with asthma symptoms worse at work or immediately following work).
   - Yes
   - No

3. **Spirometry (FEV₁, FVC, FEV₁/FVC, pre/post bronchodilator testing) consistent with asthma.**
   - Yes
   - No

4. **Peak expiratory flow rate (PEFR) done both while at work and off work for a period of 2-4 weeks consistent with WRA/OA (i.e., decreases in PEFR ≥20% compared to measurements obtained away from work).**
   - Yes
   - No

5. **Consider work-related validation with NSBP as second step.**
   - Should be done within 1 hour after work day,* and after 2 weeks of work exposure, compared to 1-2 weeks away from exposure.
   
   (Not required to confirm diagnosis.)

   Further testing may be needed for definitive causation (e.g., management or medical removal) for OA. Determine triggering exposure, e.g., specific allergen for HMW or LMW sensitizer induced OA, and source of high dose exposure.

6. **If patient has asthma and demonstrates sensitization to allergen used in the workplace, the diagnosis is established.**

7. **Sensitizer-Induced OA**
   - Skin prick testing or specific immunological testing (e.g., IgE for well-known and commercially available antigen).
   - Positive
   - Negative or Not Available
   - Consider specific inhalation challenge (SIC) testing (highly specific use).
   - Positive
   - Not available

8. **Irritant-Induced OA**
   - Treat asthma, limit irritant exposures.
   - Consider causes of false negative SIC (wrong agent, wrong concentration, wrong duration of exposure, too long out of exposure).
   - If clinical history compelling for OA despite negative SIC.

9. **Work-Exacerbated Asthma**
   - Treat asthma, limit irritant exposures.
   - If true negative, consider other airway associated disorders.
   - Cessation of exposure for 6 months. Evaluate monthly.

---

*In the absence of ongoing suspect exposure, the relationship between airway reactivity and the suspect agent can only be confirmed with SIC; this may be the only absolute indication for performing a specific bronchial provocation challenge with a diisocyanate and is justified if the result will have an impact on future health and economic outcomes.

*This step can be omitted if NSBP already completed.*
MEDICAL HISTORY
Taking a thorough medical history is the first step when suspecting occupational lung disease. The history should include three components: 1) current and previous respiratory symptoms; 2) an occupational history that includes a detailed exposure history; and 3) focused questions linking the symptoms to the workplace, in space, time, and latency from first exposure. The ultimate goals of a structured investigation are to assist in determining causation, implementing treatment, and intervening to prevent disease in other exposed workers.\(^{(49)}\)

The patient should be queried regarding childhood respiratory symptoms, as well as colds, bronchitis, pneumonia, hay fever, sinus problems or allergies. Evidence for atopic disease should be sought (e.g., asthma, hay fever, and eczema).\(^{(50)}\) Ask about the length and severity of these illnesses, medication history, and whether emergency department treatment or hospitalization was required. Some studies show that atopy increases the risk of WRA or sensitization for certain asthmagens including enzymes, isocyanates, animals, bakery allergens, dyes, green coffee, castor bean, certain shellfish, and acid anhydrides.\(^{(51)}\) While family history is important in asthma incidence, the same family history does not reliably predict occupational lung disease in exposed workers.\(^{(52)}\)

A history of asthma symptoms arising during a period of employment, especially with improvement on the weekends or holidays is suggestive of WRA. However, more evidence is needed to verify that the symptoms are due to asthma, and that the asthma is related to workplace exposures.\(^{(27)}\)

Although the probability of WRA from history alone is not high, a typical history consistent with WRA can lead to a pretest probability as high as 70% before diagnostic tests are conducted.\(^{(7)}\) Cote, et. al., reported that a history suggestive of western red cedar asthma had a diagnostic specificity of 45%.\(^{(53)}\) In contrast, Malo et al., reported that 76% of referred clinical patients reported improvement in respiratory symptoms while away from work but were subsequently found to have no objective evidence of WRA.\(^{(49)}\)

Taken together, the clinical history is believed to be more reliable for excluding than confirming the diagnosis of WRA.\(^{(9)}\) For OA without latency, frequently resulting from accidents or other non-routine workplace conditions, the history is often the primary source of information to establish that a highly offensive atmosphere was present. In this section, we will use the words inflammatory or irritating interchangeably.

INTERVIEW QUESTIONS
Larger employers often have the benefit of workplace surveillance programs, medical staff on location, accessible spirometry, and general knowledge of the chemicals used in the work environment. This may allow a more focused history than the general recommendations below. Symptoms of occupational asthma include episodic wheezing, chest tightness, cough, dyspnea, or recurrent attacks of bronchitis with cough and sputum production. The history\(^{iv}\) should include the following questions:

1. **What are your symptoms?**
   - What are your symptoms of concern? Do you have cough, shortness of breath, or wheezing?
   - When did these symptoms first occur? Was there an event that precipitated the symptoms?
   - When did these symptoms first occur relative to the beginning of your work in that location?
   - How frequently have symptoms occurred?
   - Do they get worse at any particular time of day or night?
   - If yes indicate below the patterns of the symptoms:
     - Do these symptoms ever begin immediately after starting work (less than 1 hour)?
     - Do these symptoms begin hours after starting work?
     - Do these symptoms continue or start while at home?

\(^{iv}\)History for asthma does not replace the OSHA questionnaire when required by regulations. See OSHA Respiratory Questionnaire Appendix C to Sec. 1910.134: OSHA Respirator Medical Evaluation Questionnaire.
- Do they improve when you are away from work such as on weekends, nighttime (off-shift) or holidays or vacations?
  - Are your symptoms constant or intermittent? What makes them worse or better?
  - Has the pattern of your symptoms changed over time? How?
  - Is there a seasonal pattern to your symptoms? What time of year are they the worst?
  - Are the symptoms associated with any substance or process at work?
  - How frequent and severe are your symptoms? Have your pulmonary symptoms included throat tightness, difficulty with inspiration or expiration, harsh sounds, cough, or sputum production?
  - Did any emergency room or physician visit document lung function?
  - Do you have a history of pre-existing asthma, (in particular childhood asthma which can recur in adults), including prior frequency of symptoms, treatment with asthma medication and response to medications?
  - Do you have a history of allergy or has anyone mentioned the word atopy to you?
  - Do you have symptoms of allergic rhinitis and/or conjunctivitis that are worse with work?
  - Did the symptoms begin after a one-time, high-level workplace inhalation exposure to an irritant gas, fume, smoke or vapor?
  - How does medication use affect the symptoms? Do you use prescribed medications, over-the-counter medications and/or complementary/alternative preparations? Do you use pulmonary and non-pulmonary medications? Are you taking an angiotensin converting enzyme inhibitor? Beta-blocker?
  - Do others at work have the same symptoms you have?

2. **How did your condition develop?**

**PAST:**
- Have you had previous similar episodes before your current job?
- What kind of treatment did you receive for these symptoms in the past?
- Who was your physician?
- Were the treatments effective?

**CAUSE:**
- What do you think caused the problem?
- How do you think it is related to work?

**OCCUPATIONS AND ACTIVITIES:**
- What do you do for work?
- Current occupation and specific work activities including shift, hours, duration, and days worked per week. (Patients working 6 days a week or more may not have enough time away from work to symptomatically improve.)
- Any past work history including specific activities, especially if there is a history of similar symptoms?
- What chemicals or substances including gas, fumes, vapors, dusts, or aerosols do you work with? What about at home?
- What is the work area’s room size, specific ventilation, other co-worker reports, exhaust hoods, remodeling, and recent change in processes? Are there Material Safety Data Sheets (MSDSs) and industrial hygiene reports available?
- Were there changes in work processes in the period preceding the onset of symptoms? Symptoms of asthma that develop or worsen after a worker starts a new job or after new materials are introduced on a job are suggestive. (A substantial period – from months to years – can elapse between initial exposure and development of symptoms.)
- Was there an unusual work exposure before the onset of initial asthma symptoms?
- Do you have any protective equipment at work, such as masks or respirators? How often do you use them? Are they required?
- Do you have a second job (moonlighting)?

NON-OCCUPATIONAL ACTIVITIES:
- What is your home environment including any hobbies, crafts, pets, family members who work with chemicals, family members who smoke, living near an industrial plant, or living near congested traffic area? [54]
- What are your leisure activities (e.g., woodworking, gardening, welding, etc.)?

3. How do these symptoms limit you?
- Are there any activities that you can no longer perform?
- Do you feel more short of breath during exercise?
- Do you feel more short of breath when doing normal daily activities?
- How long have your activities been limited?

4. Do you have other medical problems?
- Do you have headaches, fatigue, malaise, weight loss, appetite changes, fever, physical abilities and exercise intolerance?
- Do you have any autoimmune, infectious, or metabolic diseases?
- Do you have any allergies?
- Do you have any other respiratory diseases or conditions?
- Do you smoke? Does someone else in your environment smoke?
- Do you use other drugs, including marijuana?
- Do you have diabetes or HIV?
- Have you ever had cancer?

5. What are your expectations regarding your return to work and disability from this health problem?

6. What are your concerns about the potential for further injury to your lungs?

7. How do you like your job, your supervisor, and co-workers? What is your relationship with your co-workers and supervisor and how do they treat you?

8. What do you hope to accomplish during this visit? [13]

Standardized Questionnaires
There have been general articles and questionnaires used to document occupational illness. [55, 56] Similarly, authors have suggested questions targeting work-related pulmonary conditions. [57, 58] Questionnaire adequacy measures have shown instruments that are reliable, valid and correlate with testing. [59-63] Reliability should be considered as reproducibility of response and validity is a measure of how well the instrument measures the intended target. Ultimately, there have been investigations looking at correlations between history and diagnosis of occupational lung disease. [64] Malo, et al., examined the accuracy of the medical history in 162 workers referred for evaluation of occupational asthma, using specific inhalation challenge to confirm the diagnosis. They reported a positive predictive value of 46% and negative predictive value of 83%. In a study by Baur, et al., who used methacholine testing and specific bronchoprovocation challenge, the predictive value of the medical history was 90% with a negative history and 30% with a positive history. Vandenplas, et al., reported a specificity of 14% and sensitivity of 87% in natural latex workers when compared to specific inhalational challenge testing for diagnosis of OA. [65]

All instruments have limitations that will miss true cases of occupational asthma. [49, 66] The American Thoracic Society Division of Lung Diseases (ATS-DLD) instrument [67] is the most widely used questionnaire for pulmonary symptoms and disease that is validated in the literature.
Family History
A family history of atopic diseases may help identify individuals with greater susceptibility to occupational asthma with latency, particularly for occupational asthma to high molecular weight agents. However, it is important to note that many workers with occupational asthma will have no family history of atopy, and conversely, many workers with an atopic history without occupational asthma. A history of similar symptoms in other household and family members may also help identify non-occupational causes of asthma, such as home and hobby exposures.

Occupational History
The physician should obtain an accurate and detailed history of current and prior occupations. All possible occupational exposures should be identified, especially those that are known to induce airflow obstruction (e.g., animal and plant proteins, organic dusts, proteolytic enzymes, specific chemicals such as isocyanates and anhydrides, noxious fumes, metals and drugs). Both routine and episodic tasks are potential exposures and should be evaluated.

The physician should also attempt to quantify the exposure. The intensity (duration and concentration), frequency, duration, and peak concentrations of the exposures are all important to document if possible. A detailed history of current exposure status is important. Lam, et al., reported a significant improvement in spirometry results after a mean of 0.8 years after removal from exposure in patients with occupational asthma.

EXPOSURE ASSESSMENT
Respiratory injury is dependent upon both the site of toxin deposition and the type of cell and structure damaged. The concentration and chemical properties (pH, water solubility, reactivity) of the substance involved are relevant, as they affect the site of deposition. The degree to which a given inhalational exposure results in disease not only reflects the intensity, duration, and type of exposure, but also varies based on host factors such as genetic susceptibility, comorbid conditions, and lifestyle factors and habits (e.g., cigarette smoking). The presence of work-related pulmonary conditions should include assessment of whether representative measurable environmental determinations exist, to ascertain whether there has been sufficient exposure to affect the lungs. However, measurable environmental determinations are not routinely performed in most workplaces, and when performed, represent a brief snapshot of selected exposures that may or may not reflect the relevant work exposures.

Information on work exposures may be obtained from MSDSs, industrial hygiene data, employer records, and union health and safety personnel information. In general, at least one source of objective information is needed for evaluation of cases of suspected occupational asthma. The MSDS is usually the initial source of information, although sensitizing ingredients in low concentrations may not be listed, and identifying them may require a phone call to the technical staff of the manufacturer. Published literature may also be helpful.

It is important to establish:
- All known exposures in any environment to any chemicals or substances including gas, fumes, vapors, dusts, and aerosols, particularly known or suspected asthmagens.
- Workplace history of room size, ventilation, current and past use of personal protective equipment, other co-worker reports, exhaust hoods, remodeling, recent change in processes, and industrial hygiene reports (if available).
- MSDSs should be reviewed, if available, for both health effects information and personal protective equipment recommendations by the manufacturer of materials used.

For exposure assessment, the standards and methods of evaluation widely used are those promulgated by the American Conference of Governmental Industrial Hygienists (http://www.acgih.org). In particular, the group’s biological exposure indices and threshold limit values are more frequently evaluated and...
updated than those occupational exposure levels (OELs) from the Occupational Safety and Health Administration (OSHA), the Mine Safety and Health Administration (MSHA), and the permissible exposure limits (PELs) defined by the National Institute for Occupational Safety and Health (NIOSH). OELs are set primarily to provide a means for standardized hazard assessment of a material, communicate a relatively safe target concentration relative to time interval which can be verified quantitatively, and to provide a target control approach to ensure that workers are not overexposed.

For workplace risk assessment, the NIOSH Pocket Guide to Chemical Hazards provides a concise summary of toxicologic information. Most inhaled particles with a diameter of greater than 3 µm are deposited along the airways of the upper and lower respiratory tract. Smaller particles may penetrate the alveolar region, but the physical characteristics, total mass and chemistry of the particle and airway structure and airflow must be considered. Water soluble gases, vapors and aerosols are usually deposited in the upper airway, while water insoluble substances affect the lower airways or lung parenchyma. Extremes of pH also are associated with severity of injury. Of importance in evaluation of respirable exposures is the distance of the worker from the source. The area tested should usually be within 2 feet of the worker’s mouth and nose. The probability of exposure is evaluated by considering: 1) the presence, form and biological availability of potential hazards; 2) confounding exposure factors in the workplace or the patient’s medical and occupational history that may account for other exposure potential and experience; 3) non-worker controlled factors such as materials used, ventilation, hazard control, and physical barriers; 4) the worker’s use of employer-selected personal protective equipment (i.e., respirators, gloves) and training in appropriate work practices; and 5) the presence or absence of illness in co-workers with similar exposure potential.

Environmental History
Exposures outside the workplace are also important to evaluate and document. Patients should be queried regarding primary place of residence, its age, location, type, remodeling history, heating, ventilation, flooring, and past water damage. Hobbies such as automobile repair, woodworking, photography, ceramics, and gardening may expose individuals to agents that can cause or exacerbate asthma. The majority of the U.S. population is skin-test-positive to at least one environmental allergen. It is difficult to determine the relative contribution of work-related and non-work-related factors to the genesis of symptoms in people with multiple risk factors or exposures.

Smoking History
The greatest threat to personal lung health is from tobacco inhalation. Although it is customary to quantify tobacco use in terms of pack-years, the variation in cigarette type and inhalational habits does not permit more than an approximation for potential lung injury. Cigarette smoking is a recognized risk factor for common airway diseases with the unusual exception of diisocyanate asthma. The smoking history should quantify the packs per day and the years smoked. Cigarette smoking may have an additive effect to airways obstruction from other causes, it may superimpose additional symptoms, or it may lead to misdiagnosis if the condition is apportioned disproportionately to smoking. Cigarette smoking may condition or modify the response to some antigens but this is not known at this time and cannot be assumed. Regardless of the history, a physical examination and diagnostic testing should be conducted as indicated.

Physical Examination
The art of physical examination traces its modern roots to the introduction of the stethoscope by Laennec in 1821. Standard textbooks provide guidance on pulmonary examination. In general, an occupational pulmonary physical examination should include elements of the following:

- Inspection for stigmata of pulmonary disease as well as potential etiologies including mucous membrane abnormalities, nasal polyps/swelling, clubbing, nasal flaring, nasal crease line, accessory muscle use, AP diameter;
- Palpation primarily for chest wall abnormalities, tracheal deviation or tactile fremitus;
- Percussion for resonance to identify aeration, diaphragm level, suggestion for fluid interface or consolidation;
- Auscultation for inspiration to expiration ratio, breath sounds including crackles, wheeze and bronchi;
- Cardiac examination; and
- Dermal examination.\(^{(81)}\)

However, a shift has occurred in medicine where physical diagnosis is often measured against a technologic gold standard for the presence or absence of disease. Thus, a useful measure of an examination would be the likelihood of a finding causing a change in the probability of a disease. Numerically the likelihood ratio is equal to the probability of a finding in patients with a disease/probability of a finding in patients without a disease. For example, it is often taught that the crackles of fibrosis are late and fine whereas those of COPD are early and coarse. Yet, this assumption has never been rigorously tested. On the other hand, diagnostic pneumonia findings have been subjected to numerous studies and are incorporated in both diagnosis and prognosis.\(^{(82-84)}\)

Formal spirometry testing and interpretation is covered elsewhere. Many clinicians will utilize simple clinical tests as part of their “physical examination.” This includes obtaining a simple pulse oximetry reading and/or having the patient walk in the hallway to identify desaturation.

**DIAGNOSTIC TESTING**

**SPIROMETRY TESTING**

**Use of Spirometry in WRA**

Spirometry testing is an essential component in the evaluation and management of persons with possible work-related asthma.\(^{(85-91)}\) Spirometry with or without bronchodilator administration has four distinct potential roles when WRA is a concern:

- Determining whether asthma is present;
- Exclude other “asthma-like” conditions;
- If asthma is present, helping inform the conclusion about whether the asthma is work related; and
- Monitoring response to therapy (and possible return to work).

Indications for spirometry with or without bronchodilator for the evaluation of work-related asthma include signs and symptoms associated with a history consistent with work-related asthma (e.g., a worker experiencing chronic or intermittent cough, chest tightness, wheezing or dyspnea, occurring at the workplace or developing over several hours following the end of a work shift or awakening from sleep, which may or may not be obviously associated with the same location, product, process, or activity, or change in asthma medication use pattern).\(^{(85, 92-94)}\) Spirometry with bronchodilator is an essential test for the evaluation of pulmonary function and would be performed in most cases whether or not occupational asthma is under consideration. Evidence for the utility of spirometric testing in the diagnosis and management of general asthma is summarized in other evidence-based guidelines.\(^{(94, 95)}\)

Spirometry is also included in other more specialized tests discussed later in this document. These include measurement of airway reactivity (e.g., methacholine, mannitol, or histamine challenge) and specific inhalation challenge (SIC). Variability of airflow obstruction fundamentally distinguishes asthma from other obstructive disorders. Comparison of spirometry results before and after administration of a bronchodilator and variability of results when repeated over many days are effective and simple methods of assessing such variability.
When considering WRA, spirometry with bronchodilator is used primarily to document and quantify airflow obstruction. For this purpose, the forced expiratory volume in one second (FEV₁) and the ratio of the FEV₁ to the forced vital capacity (FEV₁/FVC ratio) are most useful. The average flow rate during the midportion of the expiratory maneuver (FEF₂₅-₇₅%) may occasionally be useful.

Asthma is confirmed by demonstrating airflow obstruction (e.g., by reduction in both FEV₁/FVC ratio and FEV₁) or by a positive metacholine challenge. Methacholine challenge testing is a specific test for airways reactivity in which FEV₁ is used as the test outcome, but it cannot clarify the work relationship or the particular antigen involved in work-related asthma. Repeated spirometry, or spirometry followed by repeated peak flow measurements, is used to demonstrate that the obstruction is present and that it is variable rather than fixed.

Methods
Accurate results depend upon use of proper equipment, proper test performance, and qualified interpretation. Considerations for spirometry quality assurance are not specific for WRA, and several excellent reviews are available. OSHA has also recently issued guidance on best practices for occupational spirometry testing. ACOEM has emphasized the critical role of obtaining accurate data. The figures below illustrate common pitfalls.

**Figure 1. Error: Inconsistent Zero-Flow Errors Causing Flows to be Over-Recorded**

DELETE THIS TEST. This spirometer’s zero-flow reference point was set at different incorrect levels before the first two maneuvers, causing the volume-time curves (bottom figure) to be splayed apart. FVC is more increased than FEV₁, falsely reducing the FEV₁/FVC and probably leading to an erroneous “obstructive impairment” pattern. Block sensor when the spirometer is zeroed and hold sensor still during subject testing to avoid this problem.

Figure 2. Error: Excessive Hesitation (solid curves)

DELETE THIS TEST. Since the worker's initial blast is delayed, the peak of the flow-volume curve (top figure) is displaced to the right, and a gradually climbing tail is seen at the start of the volume-time curve (bottom figure). Coach the worker: "BLAST out as soon as you are ready."

Figure 3. Error: Early Termination (solid curves)

When an expiration stops before the volume-time curve flattens into a 1-second plateau, the FVC may not be fully recorded. An incompletely recorded FVC will falsely increase the FEV₁/FVC and may cause the spirometer interpretation to be “normal” even when airways obstruction is present. The solid lines show the curves that were terminated early. The dashed line shows the increase in “FVC” that would have occurred with only 5 more seconds of expiration. The more accurate FEV₁/FVC recorded after 10 seconds would trigger a correct interpretation of “airways obstruction.” (Note that no more than one maneuver should be recorded for longer than 15 seconds.) Coach “Keep blowing until I tell you to stop.”

Figure 4. Cough in First Second—Invalid Test (Must be Deleted)

Cough in the first second produces steep interruptions in the flow-volume curve and subtle steps in the first second of the volume-time curve. Coughs often reduce the FEV1. Try offering a drink of water to solve this problem.

Spirometry can be done alone or with pre- and post-bronchodilator testing. Pre- and post-bronchodilator testing is performed by establishing baseline airflow and then determining whether volumes increase with administration of a bronchodilating agent (usually albuterol, known internationally as salbutamol, a short-acting beta2-receptor adrenergic agonist).

The American Thoracic Society (ATS) defines a 12% improvement in the FEV1 or an absolute value increase of at least 200 mL after bronchodilator administration as indicating reversibility of airflow obstruction in FVC or FEV1 values.(6, 27, 90, 94, 95, 99-101) Rarely, subjects may have a paradoxical response to the bronchodilator resulting in increased obstruction; this is a transient effect associated with highly reactive airways responding to a nonspecific stimulus and slow response to the agent. Changes in peak flow are to be expected and are used to monitor progress in treatment but not for diagnosis.

Spirometry is difficult for some patients to perform, and irreproducible results may make interpretation difficult.(102) (Allen 09) Using spirometers that show large real-time graphical displays, testing should be performed by a technician who has completed NIOSH-approved spirometry course.(98) Up to eight maneuvers may be attempted (beyond which most subjects tire) to produce three acceptable tracings, and the difference between the highest and second highest FVCs and FEV1s should be within 0.15 of each other to achieve consistent “repeatable” results. The highest values of FVC and FEV1 are used to summarize the patient’s lung function, regardless of whether they are drawn from the same or different curves. Inability to perform reproducible tracings is often due to failure to cooperate or poor effort because, properly performed, spirometry achieves a physiological limit on flow that is beyond voluntary manipulation. A small number of subjects will not be capable of producing reproducible tracings due to behavioral problems, poor neuromuscular coordination, or very low lung function. Such subjects often have a poor prognosis for survival and for future disease, even if their pulmonary function are within or close to the normal range.(102-104) The American Thoracic Society and European Respiratory Society (ATS/ERS) have published 4 statements since 1979 on how to conduct spirometry tests and 2
Proposed Occupational/Work-Related Asthma Guideline
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)

Statements since 1991 on how to interpret results.\(^{(95,105)}\) Since 2000, ACOEM has published three comprehensive spirometry statements on conducting and interpreting tests – most recently in 2011.\(^{(96)}\) These statements emphasize the importance of performing and interpreting the results correctly.

**Interpretation of Spirometry**

Spirometry with or without bronchodilator cannot differentiate occupational asthma from non-occupational asthma, and must be interpreted with additional information from the history or supplemental testing.\(^{(106)}\) Failure to demonstrate reversible airway obstruction on a single test day does not exclude the diagnosis of asthma or of airways reactivity in general.\(^{(92,94)}\)

Important caveats to consider:
- Failure to demonstrate reversible airway obstruction on a single test day does not exclude asthma.
- Serial measurements can be used with clinical correlation to track progression and variability under different conditions and exposures, with the understanding that improvement in the measurements does not always correlate well with an improvement in the disease.
- Because asthma is characterized by variability, airflow obstruction is an indicator of status at any one time and does not necessarily reflect trends over time, but can indicate worsening of disease if it is much worse than a previous FEV\(_1\) measurement.
- Therefore, its main value is in demonstrating variability (e.g., ruling out irreversible obstruction).\(^{(27,85,94,95,99,107)}\)

The measurements of greatest utility in spirometry for the evaluation of airways disease are:\(^{(97,99)}\):
- Forced expiratory volume in one second (FEV\(_1\)), expressed in liters and/or as a percentage of predicted values,
- FEV\(_1\) before and after (pre/post) administration of a bronchodilator, usually albuterol (salbutamol),
- Pre/post FEV\(_1\), which is measurement of FEV\(_1\) before and after (pre/post) a work shift, taking into account diurnal variation,
- Ratio of FEV\(_1\) to forced vital capacity (FEV\(_1\)/FVC), expressed as a percentage,
- Peak expiratory flow (PEF), expressed primarily in liters per minute, which is particularly useful in following workers in whom reactive airways are demonstrated, and
- Of less central importance, forced expiratory flow rate (FEF\(_{25-75}\)), which is the volume expired between 25% of FVC and 75% of FVC, often called midflows (see limitations below).

Variability in appropriate spirometry measures in testing separated in time (days) or in response to bronchodilators (most accurately for FEV\(_1\)) indicates asthma. Fixed airways obstruction is present when volumes are unchanged, within limits of the test.

While FEF\(_{25-75}\) is a measure of airflow through smaller airways, structures that are commonly and disproportionately affected by cigarette smoking, FEF\(_{25-75}\) tends to vary far more than the FEV\(_1\) both within and between healthy individuals, and so it is difficult to interpret abnormality of this flow rate in individual patients. When early emphysema is present, airflow in small airways is disproportionately reduced and is less variable than in asthma, but standards for this interpretation have not been established. Since 1991, ATS has discouraged using the FEF\(_{25-75}\) to diagnose small airways disease in individual patients when the FEV\(_1\) and FEV\(_1\)/FVC are in the normal range.

Spirometry with bronchodilator is not invasive, has few adverse effects and is low to moderate cost and high in yield for complications and other respiratory problems. Its value comes in correlation with clinical information and observation. Spirometry with bronchodilator is thus recommended as an integral part of the evaluation of work-related asthma.
PEAK EXPIRATORY FLOW RATES (PEFR)

Peak expiratory flow rates (PEFR) is defined as the maximum flow achieved during expiration, delivered with maximal force, starting from the level of maximum inspiration and using simple portable meters. Serial PEFR measure the circadian rhythm, which has lower values in the early hours of the morning and maximal in the afternoon. The differences are more pronounced in individuals with bronchial asthma.\(^{(108)}\)

The use of PEFR is common in the diagnostic investigation of asthma including work-related asthma and occupational asthma. PEFR is most readily performed via a hand-held peak flow meter providing air flow measurement in liters/minute, and must be performed by the patient outside of a medical setting to be useful in evaluation of occupational asthma.\(^{(109-111)}\) Thus, PEFR can be easily obtained both at and away from work to document presence or absence of changes in flow that are potentially related to the workplace environment or exposures.

**Recommendation: Peak Expiratory Flow Rates – Serial Measures**

Serial peak expiratory flow measurements are moderately recommended as an initial evaluation method for diagnosing work-related asthma, in patients already diagnosed with asthma by other methods. The physician or qualified staff should train the patient on the proper use of the meter and the importance of accurate recordings. A meter that can store the measurements should be used when possible.\(^{(7, 81, 112-114)}\)

**Strength of Evidence** – Moderately Recommended, Evidence (B)

**Level of Confidence** – High

**Performed** – Assessment of serial measurements of PEFR at and away from work is an accessible method of confirming the relationship between the exposure and bronchoconstriction and has been recommended as a first-line investigation in suspected cases of occupational asthma.\(^{(115)}\) Standards for PEFR devices and their performance have been published by ATS and the subcommittee on Occupational Allergy of the European Academy of Allergy and Clinical Immunology group with recommendations for total duration and frequency of PEFR measurements both at and away from work.\(^{(115)}\) The optimal frequency and duration of serial PEFR has not been agreed upon. Generally, workers are instructed to record PEFR every 2-3 hours for 4 weeks, including periods at and away from work, while maintaining a diary indicating their activities, as well as, any symptoms they might be experiencing including use of bronchodilators. Dedicated diary cards are available at www.occupationalasthma.com. Each measurement session should include three or more forced expiratory maneuvers with the best of the attempts recorded and used for analysis.\(^{(1, 3, 7, 9, 108, 111)}\) The best of three PEFR readings should be recorded on each occasion provided the best two readings were within 20 L/minute of each other. A recording period of 4 weeks, including a period of at least 2 weeks away from suspect exposure is recommended, although longer periods increase the value of the test.\(^{(109-111)}\) PEFR measures should be obtained upon awakening, mid-day, at the end of the shift, and before bedtime (or comparable times for non-day shift workers), although some investigators recommend every 2 hours while awake.

There are several interpretive methods for analysis of serial PEFR data. Values must be plotted with the average reading for time of day for work and off-work periods. Analysis may be performed visually by an expert, although there is a degree of intraexpert and interexpert variability.\(^{(116)}\) Two alternative methods include difference in diurnal variability (maximum-minimum/maximum value x 100) and differences in mean PEF between work and non-work days. The difference between mean PEFR on rest days and mean PEFR on work days has been recommended as the best index for differentiating workers with occupational asthma from those with nonoccupational asthma by Anees, et al. They proposed a value of >16 1/minute as the most sensitive index to differentiate subjects with occupational asthma from healthy individuals and non-occupational asthmatics.\(^{(110)}\)
**Indications** – To assist in screening patients with a history consistent with WRA.\(^{(9, 110, 114)}\) There have been concerns over the reliability of self-reported peak flow measurements. One study found that self-recorded PEFRs were concordant with less than half of electronically stored measurements.\(^{(117)}\) Although other investigators have reported better concordance,\(^{(118)}\) these findings emphasize the importance of careful monitoring and daily supervision of workers during performance of serial PEFR measurements. Use of a freely downloadable automated data plotting and analysis system may limit human variability in interpreting the PEF values, and can be particularly useful for practitioners without extensive prior experience (www.occupationalasthma.com).\(^{(119-124)}\)

**Harms** – None.

**Benefits** – Can provide moderately objective evidence of relationship between work and asthma worsening.

**Advantages and Limitations** – PEFR is heavily dependent upon the worker’s efforts, including reliable performance of a forced expiratory maneuver, accurate recording of the results, and assumes worker honesty in performing and recording the test results.\(^{(1, 5, 90, 107)}\) In a study of 17 subjects blinded to simultaneous recording by the peak flow meter, only 55% of the records were completed accurately by the participants.\(^{(6)}\) Quirce, et al., reported that 23% of PEF readings were inaccurate and 23% of the readings were invented, although these did not tend to change interpretation of work-relatedness.\(^{(117)}\) PEF measures cannot differentiate between OA and work exacerbated asthma.\(^{(7)}\)

**Rationale for Recommendation**

There are 4 moderate-quality studies that support the use of PEFR as an investigational tool for the diagnosis of OA and work-related asthma.\(^{(109, 111, 114, 122)}\) Three studies performed compared PEFR readings to FEV\(_1\)/FVC measurements over a 4 week period in workers with a diagnosis of OA, concluding that serial PEFR measurements over a 4-week period including a period away from the workplace was moderately sensitive and specific. There is a suggested “minimum data criterion” of greater than or equal to four readings per day for more than two weeks that should be met before analysis of the data.\(^{(109, 111, 114)}\) Another study demonstrated similar results over a shorter period of time with the use of a specific analysis tool.\(^{(121, 122)}\) There is evidence that both supervised and unsupervised PEFR methods are acceptable, and thus no recommendation for or against a particular method is made, and is left to the discretion of the treating physician for each particular patient.\(^{(107, 125)}\) There is one high-quality study demonstrating poor sensitivity with a cross-shift technique.\(^{(113)}\) PEFR is non-invasive and is low cost. Serial PEFR is recommended as an initial method for investigating suspected OA and WRA. It is desirable to initiate serial PEFR early in the evaluation of WRA when patients are more likely to still be exposed to a putative cause of asthma. Serial peak expiratory flow measures are relatively inexpensive, have a low risk of adverse events, and may add information on airway resistance both at work and at home and are thus recommended. This recommendation is downgraded from strongly recommended to moderately recommended due to the technical challenges and the ability to manipulate the results.
Evidence for the Use of Peak Expiratory Flow Rates

There are 2 high-quality and 6 moderate-quality studies incorporated into this analysis.

**Notes:**
- PEF measurements unsupervised and requested every 2 hours. Different PEF meters used in study. Data suggest using discrete lower boundary points for PEF may help diagnose occupational asthma.
- OA diagnosis was made prior to study by non-uniform methods (i.e., specific bronchial challenges, methacholine testing, and relevant history). Data suggest OASYS-2 computer system decreases the number of PEF recordings needed in serial PEF measurements.
- OA diagnosis was made prior to study by non-uniform methods (i.e., history suggestive of OA, SIC, IGE or methacholine challenge test). Data suggest PEF measurements may aid in OA diagnosis.

</table>

**Notes:**

- The OASYS program is a sensitive tool for the diagnosis of detergent enzyme occupational asthma, but the levels of exposure and specific IgE sensitization to enzymes do not affect the magnitude of PEF response in symptomatic workers.

- OA diagnosis was made prior to study by non-uniform diagnostic criteria. Data suggest serial PEF analyzed by OASYS-2 system may aid in diagnosis of sensitization to detergent enzymes.

- Small numbers – 55% (11/20) confirmed to have occupational asthma by SIC testing. Data suggest unsupervised FEV\(_1\) not better than unsupervised PEF measures for diagnosing occupational asthma. Agents used not well described. PEF measures monitored by research staff and not done independently by workers. Data suggest for immediate asthmatic responses PEFc are comparable to FEV\(_1\) measures for decreased lung function.
NONSPECIFIC BRONCHIAL PROVOCATION TEST

Establishing the diagnosis of occupational asthma must start with the confirmation of the presence of asthma. Bronchoprovocation with methacholine, histamine, cold air, mannitol, or exercise challenge is used to establish the diagnosis of asthma, particularly when asthma is suspected and spirometry is normal or near normal. Methacholine and histamine challenges are the most commonly available tests.\(^5\) Methacholine is preferred to histamine because it is associated with fewer side effects, and lung function measurements are more reproducible.\(^1\) Nonspecific bronchial provocation testing is thought to reflect the increased sensitivity of the airways to inhaled nonspecific stimuli or irritants that is reported by many patients with asthma.\(^2\) These stimuli are thought to evoke airflow limitation predominately by an effect on airway smooth muscle, although the mechanisms preceding this effect differ. Persistence of bronchial hyperresponsiveness out of the workplace is more likely in those with longer duration of symptoms and exposure than in workers with early diagnosis and removal. Increased methacholine reactivity may resolve a few months out of exposure, but has been demonstrated to persist for more than 13 years out of exposure.

1. **Recommendation: Nonspecific Bronchial Provocation Test**

   Nonspecific bronchial provocation test (e.g., methacholine) is strongly recommended for use in diagnosing asthma if the clinical history is compelling and other tests (spirometry and bronchodilator responsiveness) are unhelpful.

   **Strength of Evidence** – **Strongly Recommended, Evidence (A)**
   **Level of Confidence** – **High**

2. **Recommendation: Nonspecific Bronchial Provocation Test**

   Nonspecific bronchial provocation test (e.g., methacholine) is moderately recommended for use in diagnosing work-related asthma as other steps are required to establish the work-relatedness of the asthma.

   **Strength of Evidence** – **Moderately Recommended, Evidence (B)**
   **Level of Confidence** – **High**

3. **Recommendation: Mannitol Bronchial Provocation Test**

   Mannitol bronchial provocation test is recommended for use in diagnosing work-related asthma; other steps are required to establish the work-relatedness of the asthma.

   **Strength of Evidence** – **Recommended, Evidence (C)**
   **Level of Confidence** – **Moderate**

**Performed** – Testing location should be experienced and technicians properly trained on performance of spirometry.\(^1\) There are two methods for inhaling aqueous solutions of pharmacologic stimuli: 1) the 2-minute tidal breathing protocol; and 2) 5-breath dosimeter protocol.\(^2\) The method of performing nonspecific bronchial provocation tests is to first measure baseline lung function and to calculate a target FEV\(_1\) that indicates a 20% fall in FEV\(_1\). Inhalation of a placebo or diluent (0.9% NaCl) is optional. Inhalation of the bronchoconstrictor agent methacholine typically starts at a concentration of 0.031 to 0.0625 mg/mL, and then increases by doubling or quadrupling concentrations up to 16, 25, or 32 mg/mL, depending on the protocol. Following each inhalation, the FEV\(_1\) is measured and the test is stopped when the FEV\(_1\) has fallen by 20% from baseline or diluent value. The response is usually expressed as a provocative concentration (PC\(_{20}\)) producing a 20% fall in forced expiratory volume in 1 second. The presence of asthma is usually defined as a ≥20% fall in the FEV\(_1\) at a methacholine dose of 4 mg/mL or below.\(^3\) Methacholine 4-16 mg/ml is considered borderline full categorization of bronchial responsiveness based on methacholine PC\(_{20}\) mg/mL dose.\(^3\)

---

\(^5\)According to ATS Guidelines for Methacholine and Exercise Challenge Testing –1999, the categories of bronchial responsiveness by methacholine dose (PC\(_{20}\) mg/mL) are as follows:

---

29
Proposed Occupational/Work-Related Asthma Guideline
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)
Mannitol testing is performed via inhalation of increasing doses of dry mannitol powder in capsules, up to 160 mg. The test is considered positive if the cumulative dose of mannitol inducing a 15% decrease in FEV₁ is 635 mg or less. The dosing is sequential, starting at 5 mg, and increasing to 10, 20, 40, 80, and 160 mg doses. The 160 mg dose may be repeated two additional times for a cumulative possible dose of 635 mg.¹³⁶⁻¹³⁹

Criteria and Standards for Use – Bronchial challenge testing should be done according to the 1999 ATS statement and the 1993 European Respiratory Society statement.⁸⁵, ¹³⁹

Indications/Contraindications – To establish the diagnosis of asthma and to aid in the diagnosis of work-related asthma. NSBP is not generally recommended if the baseline FEV₁ is <65% of predicted.¹, ⁵ Absolute contraindications for methacholine challenge testing include:
- severe airflow limitation (FEV₁<50% predicted or <1.0L), heart attack, or stroke in previous 3 months;
- uncontrolled hypertension (systolic BP>200 or diastolic BP>100); and
- known aortic aneurysm.¹²⁷

Relative contraindications include:
- moderate airflow limitation (FEV₁ <60% predicted or <1.5L;
- unable to perform acceptable-quality spirometry;
- pregnancy;
- nursing mothers; and
- current use of cholinesterase inhibitor medication (for myasthenia gravis).¹²⁷ (ATS 00)

Harms – Bronchoconstriction, transient symptoms of wheezing, cough, mild dyspnea, and chest tightness, with smaller risk for dizziness and headaches post-test.

Benefits – Accurate diagnosis of asthma.

Advantages and Limitations – Testing for airway hyperresponsiveness is relatively objective and due to its accessibility, it is used regularly in clinical practice. It is limited in differentiating occupational asthma from non-occupational asthma without additional history, testing, and information. Methacholine challenge testing is more useful in excluding a diagnosis of asthma than in establishing a diagnosis because its negative predictive power is greater than its positive predictive power.¹²⁷ Bronchial hyperresponsiveness with methacholine challenge testing may also be seen in conditions other than asthma, including smoking-induced chronic airway obstruction, congestive heart failure, cystic fibrosis, bronchitis, and allergic rhinitis.¹²⁷

Rationale for Recommendations
Many high- and moderate-quality studies have evaluated the diagnostic utility of nonspecific bronchial challenge testing in comparison to other studies including specific inhalational challenge testing, peak expiratory flow meters, and immunological testing to establish the diagnosis of work-related asthma.⁵³, ⁶⁹, ¹³⁴, ¹³⁵, ¹⁴⁰⁻¹⁶² In one study of dairy farmers, the sensitivity of methacholine challenge compared to bovine inhalational challenge in diagnosing occupational asthma was reported as 82%, and specificity of

- >16 is normal bronchial responsiveness;
- 4.0-16 is borderline BHR;
- 1.0-4.0 is mild BHR (positive test); and
- <1.0 is moderate to severe BHR.

Before using this categorization, the following must be true: baseline airway obstruction is absent; spirometry quality is good; and there is substantial postchallenge FEV₁ in response to bronchodilator.

Proposed Occupational/Work-Related Asthma Guideline
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)
Another study comparing specific inhalational challenge to nonspecific bronchial challenge testing reported a sensitivity of 57% and a specificity of 93% for occupational asthma.\(^{(148)}\)

Methacholine and histamine challenges are reported to be more reliable than other nonspecific bronchial provocation tests.\(^{(135, 160)}\) Overall, methacholine challenge testing has been reported to have a sensitivity level of around 95% in the diagnosis of asthma.\(^{(92)}\) A major caveat is that nonspecific bronchial provocation testing is not capable of reliably differentiating between occupational and non-occupational asthma.\(^{(64, 133)}\) The temporal relationship of nonspecific bronchial hyperreactivity (NSBHR) with exposure is important\(^{(163)}\) and the test should be performed either during or immediately after the work shift if possible. The authors considered a two-fold increase in the PC20 FEV\(_1\) after removal of exposure to be significant.

Methacholine challenge tests do not always remain positive after a diagnosis of occupational asthma or work-related asthma, as methacholine reactivity may wane out of exposure. In a case report, a worker with asthma secondary to toluene diisocyanate (TDI) lost his reactivity to methacholine after 2 months of removal from exposure.\(^{(164)}\) Other studies of workers with occupational asthma to TDI,\(^{(165)}\) cobalt,\(^{(166)}\) and reactive dyes\(^{(167)}\) have demonstrated persistent bronchial hyper-responsiveness in some from 5 to 13 years out of exposure. Those with asthma from HMW agents may also demonstrate persistent airways hyperresponsiveness.\(^{(168)}\) Workers were more likely to lose their methacholine responsiveness with early diagnosis and early removal from exposure after onset of asthma. Those who became asymptomatic out of exposure were more likely to revert to normal bronchial reactivity than those who reported ongoing asthma symptoms.\(^{(128)}\)

Compared to specific inhalational challenges, bronchoprovocation is less hazardous, lower cost, easier to perform, more readily available, and can be completed in less time. Therefore, it is recommended for the diagnosis of asthma, and work-related asthma, particularly when the baseline spirometry is normal yet there is sufficient index of clinical suspicion.

Although most bronchoprovocation agents cause a fall in the FEV\(_1\) by triggering bronchial smooth muscle contraction, different agents act through different pathways to achieve this effect. Methacholine acts as a non-selective muscarinic agonist on receptors on bronchial smooth muscle, whereas histamine acts through stimulation of H1 receptors on bronchial smooth muscle, or indirectly through stimulation of vagal parasympathetic reflex bronchoconstriction. Cold air leads to respiratory heat and water loss with transient hyperosmolarity in the respiratory mucosa, triggering mediator release from eosinophils or mast cells that cause the airways to narrow. Mannitol likely triggers the release of inflammatory and/or bronchospastic mediators, causing the smooth muscle of the airway to contract and resulting in airway narrowing. The exercise challenge is thought to cause inflammatory cells to release mediators such as leukotrienes, prostaglandins, and histamine that secondarily provoke airway smooth muscle constriction and a measurable fall in the FEV\(_1\).
Evidence for the Use of Nonspecific Bronchial Provocation Test

There are 9 high-quality and 22 moderate-quality studies incorporated into this analysis. There are 9 other studies in Appendix 1.

**Histamine vs. Methacholine**

- Histamine: 203 people tested, 108 random tested non-asthmatics and 95 people who reported at least a wheeze.
- Methacholine: 108 random tested non-asthmatics and 95 people who reported at least a wheeze.

#### Proposed Occupational/Work-Related Asthma Guideline

- periodo first visit. responses to BHR testing (p<0.001).
- existence of moderate-to-severe BHR. Of course, these indexes are ‘soft data’ and must be used as first approximation only.
- Methacholine airway responsiveness is the most valuable diagnostic tool for asthma. In addition, there is significant correlation between methacholine airway responsiveness and some patient symptoms.
- [W]e would recommend sReff and sGaw as the reliable parameters for classification of AHR. Additional investigations on healthy subjects and patients with asthma and COPD should be performed to compare sensitivity and specificity of body plethysmography and forced spirometry for MCH-challenge tests.
- We have shown that when used in an epidemiological study methacholine produces more measurements of No OA. No real diagnosis of asthma in 95 people who had reported a ‘wheeze or asthma’ by questionnaire.
### Proposed Occupational/Work-Related Asthma Guideline

| Anderson 2009 Diagnostic Study | Age 5-50 years | Exercise, clinical diagnosis | 5 visits | Exercise test: 
>10% fall in FEV₁ 
Mannitol: 15% fall in FEV₁ at < 635 mg cumulative dose or >10% fall in FEV₁ between tests; MCC: PC₂₀ <16 
Sensitivity/specificity of mannitol to identify EIB was 59%/65%, for methacholine it was 56%/69%. BHR mild. Mean EIB % fall in FEV₁ in subjects positive to exercise 19%, (SD 9.2), mannitol PD₁₅ 158 mg (CI: 129, 193), and methacholine PC₂₀ 2.1 mg/ml (CI: 1.7, 2.6). Prevalence of BHR same: exercise (43.5%), mannitol (44.8%), methacholine (41.6%) with test agreement between 62-69%. Sensitivity and specificity for clinician diagnosis of asthma 56%/73% for mannitol, 51%/75% for methacholine. Sensitivity increased to 73% and 72% for mannitol and methacholine when 2 exercise tests were positive. |
| Koskela 2004 Diagnostic Study | N = 10 healthy subjects vs. n = 37 asthmatic patients | Repeated after 3 and 6 months of treatment of FEV₁ values for Mannitol Challenge | Asthmatic patients coughed more during the Mannitol Challenge than healthy subjects. Cough-to-dose |

“Coughing during mannitol challenge is associated with asthma and occurs independently of bronchoconstriction. Small numbers. Patients were recently diagnosed and had more cough + sputum than dyspnea + wheeze.”

</table>

Good baseline characteristics given. Randomized trial. Study of general population with asthma. Question was for control of asthma using Mannitol testing, not diagnosis of asthma. Data suggest mannitol testing can be used to help titrate medication in mild to moderate asthma but in this study resulted in a higher dose of steroid use compared to clinical judgment with no significant difference in clinical outcomes.

Methacholine (considered gold standard) performed on 25/43 (58%) cases. All cases had hypertonic saline testing performed; 7 controls did not have methacholine or hypertonic saline testing. FEV₁ at baseline ranged from 54.2-129.0 % predicted. Data suggest mannitol challenge is a possible test for asthma in mild to moderate asthmatics.

SPECIFIC IMMUNOLOGICAL TESTING

Specific immunological testing to suspected allergens is commonly used to aid in the diagnosis of allergic rhinitis and occupational asthma.\(^{(141, 162, 182-189)}\) These tests are performed to evaluate type I (IgE) hypersensitivity reactions to specific allergens,\(^{(143, 162)}\) and can be useful in the diagnosis of certain cases of occupational asthma caused by immune or allergic mechanisms, in contrast to irritant-induced asthma. However, the presence of specific antibodies is an indicator of an immune response, and does not necessarily have a causal relationship with occupational asthmatic symptoms. Hence, demonstration of sensitization to an occupational agent by specific IgE and/or skin testing alone, without demonstrating the work-relatedness of the asthma, is insufficient to establish a diagnosis of OA.

Detection of IgE to a specific allergen is accomplished by skin prick testing (SPT), and serum IgE testing when kits are available for the specific allergen. For more information on skin testing, see section below. Three methods of detecting serum IgE antibodies have been employed to assess antigenicity to occupational antigens: 1) RAST; 2) ELISA; and 3) ImmunoCAP. This guideline, in addition to basing the recommendations on the available literature that has compared and validated a particular method, will also take into consideration the commercial availability of these assays.

The sensitizing agents known to induce occupational asthma are traditionally divided into high molecular weight (HMW) and low molecular weight (LWM) antigens. The allergens and extracts are better characterized and available for HMW antigens, and much less so for LWM antigens.

**High Molecular Weight Agents**

Occupational asthma induced by HMW agents, which are mainly proteins of animal or plant origin, is often associated with the production of allergen-specific IgE antibodies. Once sensitization has occurred, subsequently inhaled allergens bind and cross-link allergen-specific IgE present on the surface of mast cells and basophils. This cell surface perturbation triggers these cells to release an array of allergic and inflammatory mediators that give rise to the asthmatic response.\(^{(186)}\) Examples of HMW asthmagens include:

- proteins of biological origin, such as laboratory animals;
- enzymes used in the detergent or food industries;
- grain proteins found in bakeries; and
- natural rubber latex proteins prevalent in health care workers.

Such proteins are considered complete allergens, capable of causing the elaboration of specific IgE antibodies. Also, for the most part, commercial validated assays exist for most common HMW allergens; therefore, recommendations will be made for the class as a whole.

**Low Molecular Weight Agents**

Low molecular weight (LMW) agents that induce occupational asthma are incomplete antigens or haptens that become allergenic only after binding with one or more autologous serum, epithelial, or tissue proteins.

Common LMW agents include:

- diisocyanates;
- colophony fume, liberated from cored solder in the electronics industry;
- complex platinum salts; and
- the family of acid anhydrides, which are common constituents in the manufacturing of resins.

Specific IgE to the hapten-protein conjugate (frequently human serum albumin) is detectable in some but not all cases of asthma, and sensitivity varies with each agent. Several reasons have been proposed. Unlike the HMW agents that are complete antigens, low molecular weight chemicals may couple variably to a protein to form a complete hapten-protein complex. The process may form new and unique antigenic determinants that are not shared by different affected workers. Waning of the immune response since last
exposure, and the lack of standardization of laboratory assays are additional factors that make testing difficult.\textsuperscript{(190-192)} Thus, interpretation of testing results must include consideration of the sensitivity and specificity of the test for the suspected agent. For example, specific IgE antibodies have been detected to anhydride acids, trimellitic and tetrahydrophthalic anhydrides\textsuperscript{(193, 194)} but not to maleic anhydride.\textsuperscript{(195)} Although the allergic reaction to platinum salts is considered to be type 1 IgE mediated, there is no commercially available radioimmunoassay and the detection of specific IgE antibodies to complex (unconjugated) halide platinum salts by skin-prick test is considered more sensitive. Specific IgE antibodies to colophony and diisocyanates, two important causes of low molecular weight occupational asthma, are poorly characterized. No reliable method of antibody detection for colophony-fume asthma has been established.\textsuperscript{(196)} For asthma induced by diisocyanates, the presence of specific IgE antibodies to a diisocyanate-human serum albumin (HSA) conjugate is relatively insensitive, being found in less than half of clinically confirmed cases of diisocyanate related OA.\textsuperscript{(197, 198)} Investigators who have evaluated the sensitivity and specificity of diisocyanate specific IgE to diagnose occupational asthma have demonstrated an association with diisocyanate asthma, but inadequate sensitivity to be used as screening tools.\textsuperscript{(198, 199)} This difficulty may in part be caused by the variability of serologic methods used in the various studies,\textsuperscript{(200)} and in part because different antigens are formed from these highly reactive chemicals that can differ between individuals and types of exposure. Thus, no one particular antigen has been identified for all cases of diisocyanate-induced asthma.

The lack of assay standardization is an important drawback to the detection of LMW IgE antibodies, as most studies have reported results using in house assays that are not commercially available.\textsuperscript{(200)} In addition, there is no consensus in conjugate preparation, although vapor hapten-albumin conjugates have been reported as having greater sensitivity.\textsuperscript{(200)} Finally, the method of making the asthma diagnosis has varied between studies, causing difficulty in interpreting the sensitivity and specificity of serologic results.\textsuperscript{(201)}

The role of specific IgG is also unclear.\textsuperscript{(196, 200)} Studies that have investigated high molecular weight IgG antibodies among laboratory workers and bakers have found a correlation with exposure intensity, but not a significant relationship with allergic symptom.\textsuperscript{(202, 203)} IgG4, a subtype of IgG, may be associated with the development of tolerance rather than allergy. Several studies have found that specific IgG responses to diisocyanate/HSA conjugates are also generally associated with exposure\textsuperscript{(200, 204, 205)} and not disease.

**Recommendations: High Molecular Weight Specific Antigens**

1. **Recommendation: IgE Specific Immunological Testing for High Molecular Weight Specific Antigens**

   Specific immunological testing (IgE) is strongly recommended for workers with symptoms consistent with occupational asthma to certain high molecular weight specific allergens and when standardized antigens and assay protocols exist. The specificity and sensitivity of the allergens should have been evaluated in quality studies using validated test methods that are commercially available. High molecular weight allergens for which there is sufficient evidence in quality studies include flour dusts, bovine danders, laboratory, and other animal allergens. Natural rubber latex (NRL) allergy can be confirmed by serum IgE testing, but the assay does not include all potential NRL allergens, such that a negative result does not necessarily exclude the diagnosis of NRL allergy.

   - **Strength of Evidence** – Strongly Recommended, Evidence (A)
   - **Level of Confidence** – High

2. **Recommendation: IgG Specific Immunological Testing for High Molecular Weight Specific Antigens**

   Specific immunological testing (IgG) is not recommended as a diagnostic tool for select workers with symptoms consistent with occupational asthma to high molecular weight
**specific allergens.** It can be used for a marker of exposure to certain allergens, but in and of itself does not diagnose disease.

*Strength of Evidence – Not Recommended, Evidence (C)*  
*Level of Confidence – High*

**Recommendation: Low Molecular Weight Specific Antigens**

3. **Recommendation: IgE Specific Immunological Testing for Low Molecular Weight Specific Antigens**

Specific immunological testing (IgE) is not recommended for workers with symptoms consistent with occupational asthma to low molecular weight specific allergens due to low sensitivity and specificity and lack of method validation.

*Strength of Evidence – Not Recommended, Insufficient Evidence (I)*  
*Level of Confidence – Moderate*

According to the Practice Parameters of the American Academy of Allergy, Asthma & Immunology, specific allergens need documented evaluation in quality studies with reported specificity and sensitivity and using standardized antigens and assay protocols. In addition, they need to be commercially available before they can be considered reliable for routine evaluation of workers. This is not the case for LMW test antigens, which are usually prepared and evaluated in individual research laboratories and are not in general commercially available. A more detailed rationale for the recommendations follows below:

**Performance** – The assay should improve on disease prediction by demonstrating high sensitivity and specificity. Methods for testing antibodies need to be standardized, with established population norms to guide interpretation of results. Each assay needs to be performed according to the manufactures recommendations following a proper protocol for testing. The majority of LMW antigens do not have commercial assays that have been validated for specific antibody testing.

**Indications** – To be used for allergens that have been shown to have acceptable sensitivity, specificity, positive predictive value, and negative predictive value using a validated method in investigational studies. If no studies have been conducted for the agent(s), no recommendation is made.

**Harms** – None.

**Benefits** – Non-invasive relatively inexpensive method of establishing sensitization to suspect agent.

**Advantages and Limitations** – Not all occupational asthma is believed to have IgE and/or IgG mediated immune responses, but data suggest IgE is involved in subsets of symptomatically exposed workers, especially to HMW antigens. There are unique challenges with such testing for work-related asthma. The reported half-life for specific IgE in serum, the time available for specific immunological testing, is approximately 7 hours. In tissue, it has varied from a short half-life of approximately two days to 5.8-6.7 months. Specificity and sensitivity differ by allergen and time since exposure. Without accurate exposure data including time since exposure, a negative specific IgE may lead to a misdiagnosis and false conclusions about the disease. There is documented cross-reactivity between different isocyanates, which may confound the determination of causation in some cases. Different laboratories and commercial tests have not been validated with proper homogenous controls. This variability creates difficulty in creating overall recommendations for immunological testing.

**Rationale for Recommendations**

**High Molecular Weight Agents:**
Wiszniewska, et al., reported a sensitivity of 61.6%, specificity of 77.3%, PPV 71.5%, NPV 68.5% in workers with baker’s asthma to wheat flour.\(^{(210)}\) Van Kampen 2008 reported sensitivity of 61-87%, specificity of 68-94%, PPV 74-95%, NPV 56-82% in workers with baker’s asthma to wheat/rye flour.\(^{(211)}\) Another study evaluating IgE to bovine dander reported sensitivity of 82%, specificity of 100%, PPV 100%, and NPV 89%.\(^{(141)}\) A moderate-quality study reported smoking and generalized atopy also were independently significantly associated with positive IgE to grain dust \(p<0.05\).\(^{(182)}\) Platts-Mills, et al., reported IgE was more specific in workers exposed to rats with symptoms of asthma and rhinitis than IgG was.\(^{(198)}\) IgG levels were reported to show evidence of exposure to wheat flour, but did not have a correlation with allergic symptoms in bakers.\(^{(202)}\) IgE levels were also elevated in workers with self-reported respiratory symptoms compared to controls in a feed plant.\(^{(212)}\) Other studies also reported positive IgE to HMW allergens in patients diagnosed with OA by SIC.\(^{(213)}\)

**Low Molecular Weight Agents:**

Park, et al., evaluated IgE levels in patients with work-related asthma to reactive dyes.\(^{(214)}\) The authors reported a sensitivity of 53.7%, specificity 86.0%, PPV 62.9% and NPV of 80.8%. For diisocyanates, Lushniak, et al., reported a small study where IgG was a marker of exposure, but not of occupational asthma in a group of workers exposed to MDI.\(^{(203)}\) Bernstein, et al., reported a sensitivity of IgE to isocyanates of 21% and a specificity of 89%.\(^{(142)}\) Tee, et al., reported IgE related to diisocyanate exposure as highly specific, at 91-100% in patients investigated for occupational asthma and confirmed with specific inhalational challenge testing, but a sensitivity of 19-28%. Therefore, it is a useful test if it is positive, but a negative test is less informative.\(^{(197)}\) Budnik, et al., reported no false positive results with IgE or SPT testing in patients exposed to MDI with asthma confirmed by positive specific inhalational challenge testing.\(^{(200)}\)
### Evidence for the Use of Specific Immunological Testing

There are 6 high- and 12 moderate-quality studies incorporated into this analysis. There are 5 other studies in Appendix 1.

| Budnik 2013 | 8.0 | 43 | IgE to MDI by fluorescence enzyme immunoassay detection method (semi-automatic ImmunoCAP 100) | SIC, SPT, histamine challenge, spirometry, and symptoms. 10/12 (83%) had positive SIC. 4/10 (40%) had positive IgE. No SIC positive patients had negative IgE. 5/10 (50%) had positive SPT. No SIC positive patients had a negative SPT. 

- "Isocyanate-specific IgE antibodies are not always detectable but their presence can be predictive of isocyanate asthma and supportive for the diagnosis of occupational asthma. In order to better compare between the studies, the methods for the immunological analysis of the IgE and IgG antibodies need standardization and validation."
- Small numbers of positive SIC patients (10). Data suggest IgE antibody testing is supportive in the diagnosis of occupational asthma if they are found to be present. An absence of IgE does not rule out a diagnosis of occupational asthma to MDI. Results based on their own characterized conjugates which are not same as commercially available tests. |

| Tee 1998 | 8.0 | 101 | RAST IgE to isocyanates | SIC, PEF, PFT, clinical symptoms, SPT | 58 considered to have OA caused by isocyanates. 46/58 (79%) had positive SIC. Patients with SIC confirmed diagnosis: IgE RAST >2: Sn: 28% Sp: 92% IgG RAST >3: Sn: 20% Sp: 100% 

- "IgE to isocyanates is a more specific than sensitive index of occupational asthma. With a RAST score of 3 or greater, it is wholly specific and therefore diagnostic of isocyanate-induced asthma. The sensitivity of specific IgE measurement is highest when blood is taken less than 30 days from last exposure, which is consistent with the observed half-life."
- SIC done on 70/101 (69%) of workers. Some of the diagnoses made by retrospective review of symptoms. Cross-reactivity of IgE was seen. Data suggest RAST IgE testing within 30 days of exposure can aid in diagnosis of OA. Methods for immunological analysis of isocyanates Ag was RAST which is not commercially available for isocyanates. |

<p>| Cartier 1989 | 7.5 | 62 | IgE and IgG to specific inhalational | Patients who underwent up to 2 weeks IgG and IgE levels after specific exposure to specific IgG to the All patients had SIC testing and then were | Increased specific | [T]he levels of specific IgG to the |</p>

| | | | | "Our results show a prevalence of specific immunological IgE mediated reactions in subjects who develop asthmatic symptoms after a shorter time of isocyanate exposure and experienced an accidental acute exposure to MDI."

More recent types of diisocyanates (HDI and MDI) bear a satisfactory association, in terms of sensitivity and specificity, to the results of specific inhalation challenges, suggesting an immunologic mechanism involved. IgG levels are better correlated than IgE with in vitro MCP-1 testing. Data suggest in vitro MCP-1 testing could be a helpful laboratory test to confirm OA due to diisocyanates. This finding has not been corroborated in subsequent research. Controls only had in vitro MCP-1 testing performed. No blinding. In vitro MCP-1 levels test is not readily available. Data suggest in vitro MCP-1 testing could be a helpful laboratory test to confirm OA due to diisocyanates. This finding has not been corroborated in subsequent research. Small numbers. Control group with little information provided. Data suggest IgE testing is more reliable for MDI than TDI in patients with symptoms consistent with asthma. Not clear whether Phadebas PRIST kit is commercially available.
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)

Proposed Occupational/Work-Related Asthma Guideline

high concentrations of isocyanate.”
SKIN PRICK TESTING

Skin tests are used, in addition to a directed history and physical exam, to exclude or confirm sensitization in IgE-mediated diseases, including asthma. There are two types of skin testing used in clinical practice. These include percutaneous testing (prick or puncture) and intracutaneous testing (intradermal). Prick testing involves introducing a needle into the upper layers of the skin through a drop of allergen extract and gently lifting up the epidermis. Intracutaneous (intradermal) testing involves injecting a small amount of allergen (0.01-0.02 mL) into the dermis. If local tissue mast cells have surface IgE specific for the allergen being tested, it will cross-link the IgE and trigger the release of preformed histamine from mast cells which in turn causes increased vascular permeability and development of a wheal; inflammatory mediators initiate a neural reflex causing vasodilatation, leading to erythema (the flare). Test results often report the size of the wheal and the size of the flare in millimeters, as W/F mm/mm and compared to the negative saline control response. Results may also be reported on a scale of 0 to 4+, where 1+ is erythema smaller than a nickel in size, 3+ is wheal and erythema, and 4+ is a wheal with pseudopods and erythema. Testing is most often performed with various allergens placed on the skin of the volar forearm or the back.\(^{(145, 215, 216)}\) Although the back is more reactive, the difference is minimal. Prick testing methods are the preferred initial technique for detecting the presence of IgE. They correlate better with clinical sensitivity and are more specific but less sensitive than intradermal testing.\(^{(217)}\) Most of the literature suggests that with a negative skin prick test result, a positive intradermal skin test (IDST) result adds little to the diagnostic evaluation of inhalant allergy. IDST is only indicated and should be selectively used when there is a compatible or compelling history and a negative or equivocal SPT result.\(^{(218)}\) Many studies have demonstrated that the prick skin test response correlates much better with clinical allergy.\(^{(219)}\)

Skin prick testing has been used to assess allergy to asthmagens in various types of patients and occupational settings.\(^{(57, 69, 185, 214-216, 218, 220-224)}\) This systematic review will synthesize the skin prick testing literature as it directly relates to other diagnostic methods for occupational asthma, but will not incorporate the entirety of allergic skin testing for common allergens.\(^{(222)}\) Not all allergens have the same level of investigative studies to validate skin prick testing as an authoritative diagnostic test. Workers should be referred to a physician with experience in skin prick testing for interpretation to assess atopy, as well as to the potential causative allergen. Skin prick testing should be performed by trained and qualified personnel, and the tests supervised by and interpreted by a physician experienced in the technique.\(^{(219)}\)

1. **Recommendation: Skin Prick Testing to High Molecular Weight Allergens**

Skin prick testing is strongly recommended for high molecular weight allergens for select workers with symptoms consistent with occupational asthma to specific allergens and where validated, commercial skin testing extracts are available. High molecular weight allergens for which there is sufficient evidence are natural rubber latex, wheat and rye flour, grain dust, alpha-amylase, bovine danders, and laboratory and other animal allergens.

*Strength of Evidence – Strongly Recommended, Evidence (A)*  
*Level of Confidence – High*

2. **Recommendation: Skin Prick Testing to Low Molecular Weight Allergens**

Skin prick testing is moderately recommended for low molecular weight allergens for select workers with symptoms consistent with occupational asthma to specific allergens, and where skin testing extracts are available. Low molecular weight allergens for which there is sufficient evidence are reactive dyes, halogenated platinum salts, and trimellitic anhydride.

*Strength of Evidence – Moderately Recommended, Evidence (B)*  
*Level of Confidence – Moderate*

3. **Recommendation: Skin Prick Testing to Other Allergens Not Covered Above**
Skin prick testing is not recommended for allergens not covered above. When specific allergens have not been evaluated in quality studies with reported specificity and sensitivity, skin prick testing for these allergens cannot be recommended. Skin prick testing is also not recommended if suspected cause is non-allergenic.

*Strength of Evidence – Not Recommended, Insufficient Evidence (I)*

*Level of Confidence – High*

**Performed** – The performance of skin prick testing has been the subject of a practice guideline by the American Academy of Allergy, Asthma & Immunology (AAAAI) and the American College of Allergy, Asthma & Immunology (ACAAI). Skin tests should be performed with 1.0 mg/ml histamine dihydrochloride as the preferred positive control and normal saline or 0.5% glycerin-saline as the negative control. Histamine control tests should be read 15 minutes after application to determine their peak reactivity. Concurrent use of antihistamines, H2 antagonists, tricyclic antidepressants and other medications impair histamine responsiveness and may reduce the size of the skin test response or suppress it altogether. Several physiologic factors may affect interpretation of skin test results, including skin pigmentation and endogenous cortisol. Different devices used for skin testing result in variable degrees of trauma imparted to the skin, and may thereby produce different sizes of positive reactions. Thus, consistent criteria are needed to rate a positive reaction produced by different skin test devices. Positive tests are often defined as a mean diameter of wheal larger by 2-3 mm more than the negative control and/or an erythematous reaction larger than 10-21 mm. Skin tests should not be performed at skin sites with active dermatitis. Adequate equipment to treat anaphylaxis must be available, although this is very rare with prick skin testing.

**Figure 5. Percutaneous Allergy Skin Test Results: Measuring the Wheal and Flare**

> Reprinted courtesy of Dr. Hal Nelson.

Each individual extract is often prepared differently and this process should be well understood by the practitioner. Frequently, a dilute preparation of an extract that is appropriate for skin prick testing is not commercially available and must be prepared by the practitioner. The stability and potency of allergen extracts are important issues that affect skin test results. Allergen extracts deteriorate with time, accelerated by dilution and higher temperatures, and lead to smaller or absent skin test responses. Some extracts such as molds contain proteases that degrade other extracts if mixed together. Expiration dates should be checked on a regular basis. Cross-contamination or bacterial contamination should be prevented, and all extracts should be stored under cold (4°C) to ensure stability.

**Indications** – Prick skin testing should be performed with allergens that have acceptable sensitivity, specificity, positive predictive value, and negative predictive value. Allergens associated with occupational asthma and that meet these criteria include: natural rubber latex, wheat and rye flour,
grain dust, alpha-amylase, reactive dyes, bovine danders, laboratory and other animal allergens, halogenated platinum salts, and trimellitic anhydride.

**Harms** – Rare risk of severe asthmatic or anaphylactic reactions.

**Benefits** – Minimally invasive, inexpensive and has few adverse events.

**Advantages and Limitations** – Skin prick testing is minimally invasive, has few adverse events, is moderately inexpensive and is recommended for specific cases where the allergen extracts have known sensitivity, specificity and those results are reliable. The risk of fatality due to skin prick testing is extremely remote, and severe/anaphylactic reactions are rare. Nevertheless, this risk cannot be completely excluded in highly susceptible subjects, such as individuals with a history of previous anaphylactic reactions, pregnant women, those who have uncontrolled asthma, or have high degree of reactivity. Skin testing should not be performed in pregnant women and only in other high risk individuals where the consequence of the result outweighs the risk.\(^{229}\)

**Rationale for Recommendations**

Multiple studies include skin prick testing as part of the diagnostic protocol, although most include skin prick testing as a test for atopy rather than a diagnostic test for occupational asthma.\(^{222}\) However, there are 20 high- or moderate-quality studies that provide results of skin prick testing compared to specific inhalational challenge testing for the diagnosis of occupational asthma.\(^{141, 143, 145, 185, 208, 215, 220}\) For patients with occupational asthma related to enzymes used in baking and pharmaceuticals confirmed by specific inhalational challenge testing, the sensitivity of skin prick testing was 100% and specificity was 93%.\(^{211, 215, 227, 228}\) Wiszniewska, et al., reported a sensitivity of 42%, specificity of 86%, PPV 73%, NPV 61% for skin testing in workers with baker's asthma to wheat flour.\(^{210}\) In workers exposed to reactive dyes, the sensitivity of skin prick testing was 76% and the specificity was 91% for occupational asthma.\(^{185}\) In a study of platinum salt workers, SPT was used to confirm sensitization in individuals with work-related asthma.\(^{225, 230, 231}\)
**Evidence for the Use of Skin Prick Testing**

There are 8 high-quality studies incorporated into this analysis. There are 4 other studies in Appendix 1.

SPECIFIC INHALATIONAL CHALLENGE TESTING

Specific inhalation challenge (SIC), also called specific bronchial provocation test (SBPT), is performed by generating an exposure to the suspect asthmagen that simulates workplace conditions, and following the subject’s lung function for an asthmatic response. It is considered the ultimate “gold standard” for diagnosing sensitizer-induced occupational asthma, used when other methods have failed to establish the diagnosis;\(^{1-10, 12, 15, 158, 159, 187, 189, 239-249}\) or a reference standard as there is no other definitive diagnostic test.\(^{11}\) False negative results have been described if the wrong agent or dose challenge has been utilized or the sensitivity to an agent has decreased after long removal from exposure. However, this has been reported as a rare occurrence.\(^{250}\)

There are certain limitations to its use. The challenge system and equipment needed for generation of safe levels of exposure during specific inhalation challenge testing are complex and expensive.\(^{3, 6, 7, 11, 27}\) Significant problems include limited availability of test facilities and infrequent though potentially serious adverse effects.\(^{251, 252}\) There is little standardization in the method for generation and measurement of inhalation challenge material. Methods for performing diisocyanate challenges have varied from small open air rooms where the worker performs the task suspected of causing symptoms, to a closed circuit apparatus that generates vapor by blowing humidified air over the chemical contained in a flask residing in a silicon bath.\(^{146, 245}\) This technique offers distinct advantages over challenge rooms, in which wide variations in ambient diisocyanate concentrations may result in exposures above the TLVs. Due to better control of diisocyanate exposures, this method will trigger less exaggerated bronchoconstriction.\(^{71}\)

Although adverse effects are less frequent than in the uncontrolled work challenge to diisocyanates,\(^{251, 253-255}\) the safer closed circuit method is performed in few centers and is unavailable for most patients suspected of having diisocyanate or other sensitizer-induced asthma.

**Recommendation: Specific Inhalational Challenge Testing**

Specific inhalation challenge testing is recommended for use in diagnosing work-related asthma with latency for highly select cases, where the diagnosis of occupational asthma is highly suspected, but has not been established by less invasive means. This testing should only be performed in appropriately equipped facilities, with direct medical supervision throughout the testing. For this reason, the recommendation is at level “C” despite the table of evidence, see below for full rationale.

*Strength of Evidence – Recommended, Evidence (C)*

*Level of Confidence – Moderate*

**Performance** – These tests may have serious complications that include fatalities. There are few centers that can safely and accurately perform these tests, and should have the proper equipment and training.\(^{51}\) Asthmagen exposure should be done after a control day where the patient is not exposed to the suspected sensitizer and lung function is monitored for stability. The testing may be performed once, but may need to be repeated on another day or with a higher dose to identify positive responses.\(^{7}\) Patients should stop using short-acting beta 2-agonist agents 8 hours before testing and longer acting medications 24 hours before testing.\(^{114}\) Positive responses, defined as a 20% fall in the FEV\(_1\), may present in an immediate pattern (within 30 minutes of the exposure), is typical for HMW agents; a delayed pattern (2-8 hours after the exposure) is typical for LMW agents; or a dual pattern demonstrating both early and late responses to that may be present with both LMW, and some HMW agents.\(^{256}\) Full method and criteria for positivity of specific inhalation challenges with diisocyanates may be further reviewed in this reference.\(^{257}\)

**Indications** – Most patients with suspected sensitizer-induced OA do not require this test, as their OA can be diagnosed with less invasive means.\(^{7, 244}\) The indications for SIC include: 1) evaluation of a worker who has left the workplace and is unable or unwilling to return to work utilizing serial measurements of lung function; 2) initial documentation of a new cause of occupational asthma; 3) identification of a specific causative agent when there is work exposure to multiple substances;\(^{7, 249}\) or 4) confirmation of
the diagnosis of occupational asthma and identification of causative agent, when other objective methods are not feasible, are less efficient, or have failed to provide definitive results.\(^{(258)}\)

**Harms** – Excessive bronchoconstriction and exacerbation of asthma; infrequently systemic and anaphylactic reactions.\(^{(258)}\)

**Benefits** – Accurate diagnosis facilitates management of OA.

**Advantages and Limitations** – Specific bronchoprovocation testing is not considered necessary in a worker with a history of OA in whom work-related airway obstruction is confirmed in association with exposure to an agent known to cause OA, or when the worker has been shown to be sensitized to that agent.\(^{(259, 260)}\) A specific bronchial challenge test should not be used for the sole purpose of settling medico legal issues.\(^{(259)}\) Limitations to the validity of the SIC include: 1) the challenge exposure does not replicate the work exposure; 2) the OA is caused by a mixture of agents, and not one single agent; 3) the worker has been out of exposure for too long, and has lost immediate reactivity to the agent; 4) the patient has unstable asthma with variations in airflow independent of exposure.

**Rationale for Recommendation**
There are numerous high- and moderate-quality studies evaluating the use of specific inhalational challenge testing as a confirmatory test for the diagnosis of occupational asthma.\(^{(6, 49, 53, 64, 113, 114, 125, 141, 146-152, 175, 187, 199, 213, 221, 240-243, 249, 261-272)}\) Specific inhalational challenge testing is expensive, time consuming, requires specialized sophisticated equipment, and has a considerably higher potential for adverse events than other diagnostic testing. While there are strongly supportive research studies that have been published suggesting level (A) recommendation, the major limitations and complications warrant downgrading to a recommended (C). SIC is recommended only for highly select cases, particularly where assurance of an accurate diagnosis is important.\(^{(185)}\)
Evidence for the Use of Specific Inhalational Challenge Testing

There are 4 high-quality and 16 moderate-quality studies incorporated into this analysis. There are 12 other studies in Appendix 1.

In conclusion, isocyanate-asthma is an important cause of occupational respiratory disease...baseline airway responsiveness to methacholine is similar in subjects who developed an immediate, a dual, or a late asthmatic reaction.”

Data suggest that clinical diagnosis based on history is only accurate about 50% of the time. SIC is considered the gold standard for diagnosis.

Small numbers. Diagnosis of workplace symptoms not well delineated in differentiating possible other exposures. Data suggest challenge testing may reproduce symptoms in patients with suspected allergy to cellulose.

Protocol varied slightly between patient groups. Data suggest late asthmatic reaction is likely an earlier form of occupational

**Proposed Occupational/Work-Related Asthma Guideline**

MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)
There is also no way to predict who will deteriorate. A decrease in the amount of exposure to cedar dust does not prevent deterioration of asthma. This suggests that the ideal management of cedar asthma is removal from exposure.

| Palczynski 2000 | 5.0 | 37 | Single blind exposure to phosphate buffered saline, then 7 days later exposure to latex protein. All done by nasal pool method and touching latex with skin. | SPT, Symptom score, RAST results, Spirometry | A = 16 nurses with either rhinitis or asthma related to latex vs. B = 9 nurses with rhinitis or asthma not related to latex vs. C = 6 patients with evidence of atopy vs. D = 6 healthy patients with no evidence of atopy. | None | Allergen challenge produced symptoms of rhinitis in all. Symptoms of rhinitis more severe in group A vs. group D (p = 0.001). Total leukocyte count in nasal washings highest in group A than other groups (p<0.001). | “The nasal challenge test appears to be useful for diagnosing occupational rhinitis in natural rubber latex-sensitized patients.” | Small numbers. Nasal challenge testing created some form of response in all patients tested. Used skin prick testing as reference test for reactivity. Data suggest a detailed analysis of nasal lavage washings after nasal challenge test can help diagnose latex allergy patients. |
NITRIC OXIDE (FRACTIONAL EXHALED NITRIC OXIDE, FENO)

Nitric oxide (NO) is recognized as a biological mediator in humans. Measurement of total exhaled nitric oxide (FENO) is a test used for detection of endogenous inflammatory signals in childhood and adult asthmatics. FENO is acknowledged to assess pathological rather than physiological changes in asthma. Increased nitric oxide in asthmatic airways is associated with up-regulation of inducible nitric oxide synthase as well as nitrite protonation in the acid environment of inflamed airways. The fraction of nitric oxide in expired air increases with uncontrolled asthma and decreases with anti-inflammatory therapy. FENO is considered to be a surrogate marker of eosinophilic inflammation in asthma. FENO is reportedly directly related to eosinophil activity suggesting other conditions such as eosinophilic bronchiolitis will affect FENO independent of asthma status. Other factors such as smoking (generally lower), use of inhaled steroids (lower), exercise (lower), height (increase), gender (higher in males), atopy (increase), recent pulmonary infections (higher), ambient air levels of NO, and other pulmonary function testing (lower) may alter FENO results. These factors, if not well described or controlled for, may make comparisons from one diagnostic study to another difficult. A more complete list of factors which may influence FENO follows, although there is not always agreement between studies as to the direction of change. Conditions in which FENO may be increased include allergic rhinitis and eczema (atopy), cough, chronic bronchitis, COPD, airway viral illness, a nitrate-rich diet, systemic sclerosis, and exercise induced bronchoconstriction. Reductions (or reductions mixed with studies showing no change) in FENO have been reported for alcohol use, altitude, congestive heart failure, obesity, pulmonary hypertension, and spirometry. Smoking (active, passive, and cessation), caffeine, and cystic fibrosis have been reported to show both increases and decreases.

1. Recommendation: Exhaled Nitric Oxide Testing for Diagnosis of Occupational Asthma
   Nitric oxide testing is not recommended for the diagnosis of occupational asthma, as it cannot differentiate between e.g., occupational asthma and other eosinophilic lung inflammatory conditions.
   
   Strength of Evidence – Not Recommended, Insufficient Evidence (I)
   Level of Confidence – High

2. Recommendation: Exhaled Nitric Oxide Testing for Diagnosis of Asthma
   Exhaled nitric oxide testing is recommended for establishing a diagnosis of asthma when more objective evidence is needed such as in litigated cases.
   
   Strength of Evidence – Recommended, Evidence (C)
   Level of Confidence – High

   Exhaled nitric oxide testing is moderately recommended for selective use in monitoring airway inflammation in patients with moderate and severe asthma.
   
   Strength of Evidence – Moderately Recommended, Evidence (B)
   Level of Confidence – Moderate

   Performed – Recommended for the select assessment of those with moderate to severe asthma to monitor treatment and control if strict protocols are in place and the physiology of the nitric oxide testing is well understood both by the examiner and the clinician interpreting the test. There are several inflammatory phenotypes in asthma and determination of the subtype is important in understanding the results and usefulness of FENO as a test.

   Criteria and Standards for Use – Use criteria and standards as described in the ATS 2011 statement for the Interpretation of Exhaled Nitric Oxide Levels for Clinical Applications.
**Indications** – Monitoring airway inflammation. It may be of assistance in corroborating a diagnosis in patients with moderate to severe asthma when more objective measures are needed. It should not be used during acute asthma exacerbations. FENO is reported to be more accurate in patients with more inflammatory airway disease and therefore, more effective in some patients than others. Normative values are still being developed. One review article opined that a single diagnostic measurement of 35 ppb or greater in a symptomatic individual should be considered clinically significant. ATS recommends that FeNO values greater than 50 ppb be used to indicate that eosinophilic inflammation is present. Exhaled nitric oxide may also be used for sequential measurements to monitor asthma control. Studies suggest that a change of 20% in the value between visits is clinically significant. Optimum flow rates have been reported to be 50 ml/s.

**Timing and Frequency of Testing** – When changing therapy, it is recommended that FENO be measured every 2-4 weeks while the treatment plan is being modified and finalized.

**Harms** – None.

**Benefits** – Provides an objective index of airway inflammation that is minimally effort-dependent.

**Advantages and Limitations** – FENO is noninvasive and has been reported to be moderately effective in the monitoring of asthma.

**Rationale for Recommendations**

The limitation of FENO in the diagnosis of asthma includes the heterogeneity of asthma causes and subtypes. While eosinophilic airway inflammation is common, it is not always the process in asthma (i.e., neutrophilic airway inflammation). Similarly, in patients already treated with steroids, the test may be falsely negative. Thus, the importance of FENO lies in its potential to identify steroid responsiveness rather than the diagnosis of asthma. However, in certain circumstances, such as in litigation, where effort on spirometry can be in question, FENO can be used to support the diagnosis of asthma where more objective evidence is needed.

The sensitivity and specificity of FENO have not been sufficiently assessed for the diagnosis of occupational asthma. There are not any occupational allergens that have had investigational studies performed regarding FENO with determination of acceptable sensitivity, specificity, positive predictive value, and negative predictive value. However, there are multiple moderate and a few high-quality studies of FENO for testing a variety of non-occupational asthmatic patients ranging from potentially mild cases to refractory asthmatic cases. One moderate-quality study assessed steroid naïve patients and reported a sensitivity of 85% and a specificity of 90% for the diagnosis of asthma. Another study reported sensitivity of 88%. A study of steroid naïve patients reported a sensitivity of 72.2% and specificity of 70.6% for the diagnosis of asthma compared to spirometry. Fortuna, et al., reported a sensitivity of 77%, specificity of 64% in asthma patients. Kostikas 2008 reported a sensitivity of 52% and specificity of 85% when comparing young patients diagnosed with asthma to all other patients. Another study concluded that FENO is not likely to be beneficial in clinical measurement except in steroid-naïve patients. Demange, et al., reported a sensitivity of 80% and specificity of 42% in detecting patients with airway hyper-responsiveness confirmed by methacholine challenge testing.

FENO is not invasive, has few adverse effects but is moderate to high cost when used repeatedly. It is recommended for select use in moderate to severe asthma for monitoring response to asthma treatments. It is believed that controlling asthma will decrease lung inflammation therefore, decreasing the FENO levels with repeated testing.
**Evidence for the Use of Nitric Oxide Testing**

There are 2 high-quality and 20 moderate-quality studies incorporated into this analysis. There are 4 low-quality studies in Appendix 1.

| Ferrazzoni 2009 | Diagnostic Study | 5.0 | 24 | Specific inhalation challenge with isocyanate | Sham specific inhalation challenge | Subjects with suspected occupational asthma due to isocyanates (toluene diisocyanate, methylene diisocyanate, or 1, 6-hexamer methylene diisocyanate). 15 subjects had positive responses to SIC; 24 subjects had negative responses to SIC but had workplace exposure. | Examined on 5 consecutive days, then follow-up 7 and 30 days after SIC with isocyanate | FVC FEV1 Fractional exhaled nitric oxide (FeNO) pH in exhaled breath condensate (EBC) | No significant changes in FeNO in any groups after sham exposure. In SIC-positive group, FeNO increased from 30 minutes to 2 hours (45 ppb to 54 ppb) after isocyanate exposure. FeNO reached maximum between 24 and 48 hours (115 ppb to 118 ppb). FeNO still high after 7 days, NS. In SIC-negative and rhinitic group, NS changes in FeNO. EBC pH increased for both SIC-positive and SIC-negative groups. | Our results suggest that FeNO is a useful measurement in the evaluation of patients with occupational asthma, particularly when the causative agent is a low-molecular-weight compound, and the assessment of airway responsiveness on specific exposure is necessary for a diagnosis because conventional immunologic tests are not applicable to demonstrate sensitization. The analysis of the time course of FeNO changes after SIC in patients with asthma. | Good baseline characteristic comparison. Co-interventions not well controlled. Data suggest FENO is useful in diagnosing asthma related to isocyanates. | Small numbers. Included lifeguards with current asthma, not needing corticosteroid treatment, and “not in crisis.” Measurements taken at a 50ml/s flow rate. Good baseline comparisons. Data suggest FENO measurements correlate with airway hyper-responsiveness with methacholine challenge in patients with asthma.
<p>| Jang 2003 Diagnostic Study | 5.0 | 25 | Sputum exam; NO metabolites, eosinophils, and eosinophils cationic protein | Peripheral blood measurement | N = 15 patients with asthma and in control group vs. n = 10 with no respiratory problems | Unknown | FEV₁, FEV₁/FVC | Higher results in asthmatics than controls for eosinophils and were at higher levels of ECP in blood. FEV₁, FEV₁/FVC negatively correlated with sputum eosinophils, p&lt;0.01. NO metabolites (1220.3±180.2 mol/L vs. 545.6±98.4 mol/L, p&lt;0.01), eosinophils (49.5±5.3% vs. 2.7±0.5%, p&lt;0.01), and higher levels of ECP (1345.1±201.5 g/L vs. 146.5±27.5 g/L, p&lt;0.01) in sputum. | “These findings suggest that the proportion of eosinophils in sputum have more accurate diagnostic marker of airway inflammation than NO metabolites in sputum and serum in differentiating asthmatic patients from control subjects.” | Small numbers. Evaluated metabolites of NO not FENO. |
| Jang 1999 Diagnostic Study | 5.0 | 23 | Fraction of exhaled nitric oxide (FENO) | Spirometry | N = 13 patients with asthma and in control group vs. n = 10 with no respiratory problems | Unknown | FEV₁, FEV₁/FVC | Significant results in asthmatics vs. controls for higher NO metabolites for sputum (1252.5+203.3 ‘moll-’ vs. 557.2+101.5 mol I-I, P&lt;0.01) but not in serum. | “NO metabolites in induced sputum have a more valuable diagnostic value than those in serum in monitoring airway inflammation in asthma.” | Small numbers. Evaluated metabolites of NO not FENO. |</p>

NASAL LAVAGE
Nasal lavage, following nasal provocation testing, is used to assess occupational airway sensitization and allergic reactions.\(^{311-314}\) In nasal lavage, the cellular and biochemical findings in the nasal lavage fluid are analyzed for evidence of allergic reaction, including changes in the percentage of eosinophils, neutrophils, eosinophilic cationic protein (ECP), mast-cell tryptase, etc. before and after nasal provocation testing. The technique may differentiate allergic from non-allergic reactions, but does not distinguish allergic manifestations of rhinitis from asthma.

1. **Recommendation: Nasal Lavage Fluid Testing for Diagnosis of Occupational Asthma**
   Nasal lavage fluid analysis after challenge with the allergen is not recommended for the diagnosis of occupational asthma.
   
   *Strength of Evidence* – Not Recommended, Insufficient Evidence (I)
   
   *Level of Confidence* – Moderate

   Nasal lavage is recommended for select workers with symptoms consistent with occupational airways allergy to specific allergens. Those specific allergens should have been evaluated in quality studies with reported specificity and sensitivity.
   
   *Strength of Evidence* – Recommended, Evidence (C)
   
   *Level of Confidence* – Moderate

**Performed** – Testing location needs to be experienced and properly trained in technique and have cell analyzation capabilities.

**Criteria and Standards for Use** – The use of nasal lavage in clinical practice is still limited due to great interindividual variability and the lack of a standardized and validated method. Inflammatory cells, protein content and mediators can be measured in nasal lavage washings, but normative values have not been established. The types of mediators measured are not standardized but frequently include eosinophil cationic protein and mast-cell tryptase. Nasal secretions can be collected and weighed for quantifying the secretory activity, especially after allergen challenges.

**Indications** – To be used for allergens that have had investigational studies performed with acceptable sensitivity, specificity, positive predictive value, and negative predictive value. Allergens having met these criteria are animal allergens,\(^{315}\) flour,\(^{213, 264}\) chloramines,\(^{261}\) latex,\(^{262}\) and glutaraldehyde.\(^{221}\) Garbage workers have also been studied.\(^{267}\)

**Timing and Frequency of Testing** – The timing and frequency of testing has not been established. Nasal lavage is more useful in situations where subjects serve as their own controls as it occurs during nasal provocation testing or exposure at the workplace.

**Harms** – Minimal discomfort and minimal risk of coughing due to fluid aspiration.

**Benefits** – Sampling of relevant tissue for demonstration of specific allergic response.

**Advantages and Limitations** – Nasal lavage fluid testing is minimally invasive, has low adverse events, and may be high cost depending on frequency of testing. The test results do not diagnose occupational asthma but may indicate occupational airway allergy.

**Rationale for Recommendations**
There are seven moderate-quality studies that evaluated nasal lavage fluid in comparison to spirometry, skin prick testing, IgE testing and peak expiratory flow rates.\(^{213, 221, 261, 262, 264, 267, 315}\) Studies have reported significant increases in eosinophils, basophils, cytokines, and eosinophil cationic protein in

Proposed Occupational/Work-Related Asthma Guideline
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)
patients with occupational allergies after challenge testing. They have also reported decreased spirometric FEV1 values. These findings may assist with the diagnosis of occupational asthma; however, they cannot provide definitive evidence to confirm a suspected diagnosis. It is recommended for select, specific cases where there is known sensitivity, specificity and those results are reliable.
Evidence for the Use of Nasal Lavage

There are 8 moderate-quality studies incorporated into this analysis. (213, 221, 261, 262, 264, 267, 268, 315)

Data suggest increased sputum eosinophils may be a clinical test to help identify occupational asthma after exposure to allergen.
PREVENTION AND EXPOSURE CONTROL

It has been stated that “all work related asthma is potentially preventable through a tiered strategy of primary, secondary, and tertiary prevention.” Workplace exposure is considered primary prevention and consists of engineering controls, administrative controls, and personal protective equipment (PPE). Engineering controls involve eliminating the potential exposure without any need for the employees to participate. Administrative controls, such as work practices, involve processes to minimize exposure. Personal protective equipment relies on the employees’ use to decrease exposure. Prevention strategies should also include educational information regarding the risk of sensitization disorders, the importance of exposure control measures, indicators of work-related asthma, and the steps to take if asthma symptoms occur in relation to work exposures.

Exposure limits have been set by various bodies such as the American Conference of Governmental Industrial Hygienists (ACGIH) and the German MAK Commission. Control of exposure can be achieved by different control measures and a hierarchical strategy is commonly applied (see Table 4).

Substitution of an agent, for instance, can include substitution of enzymes with strong sensitizing potential by less strong sensitizing enzymes, or a change to a process that does not require the use of enzymes at all. When substitution is not possible, exposure reduction is the next best approach. Engineering controls can include isolation and enclosure to prevent inhalation of any possible irritants, or substituting a new agent that is less sensitizing. Exposure reduction can be achieved by reducing the source strength (i.e., amount or concentration emitted), modifying the formulation of the active ingredient (e.g., liquid or granule instead of powder), changing the process, or by improving general hygiene (good housekeeping). Other options are isolation of the source (enclosure or segregation), ventilation, avoidance of exposure, and use of PPE. Administrative controls can include limiting time in certain areas of the plant to decrease the amount of exposure and use PPE and respirators. Often, optimal exposure
reduction strategies consist of a combination of technical and organizational measures. In practice, exposure reduction relies on a combination of different interventions.\(^{(316)}\)

The relationship between the level of exposure to allergens and the occurrence of sensitization or work-related asthma has been studied for detergent enzymes,\(^{(318-323)}\) baking operations,\(^{(324-330)}\) wood dusts,\(^{(331)}\) platinum salts,\(^{(225, 231)}\) laboratory animals,\(^{(196, 332-335)}\) anhydrides,\(^{(336, 337)}\) diisocyanates,\(^{(338-340)}\) and shellfish.\(^{(341, 342)}\) Exposure response relationships indicate that implementation of primary preventive measures in the workplace that result in a reduction of exposure should also lead to a reduction in sensitization rate. However, the effect of exposure reduction measures has not been frequently studied in practice. Thus, relatively little is known about the effectiveness and efficacy of many possible exposure reduction measures.

The most convincing example of the beneficial effects of an exposure intervention is exposure to latex allergens. For natural rubber latex (NRL), a meta-analysis is available reviewing several studies that explored differences in exposure levels between health care workers using powdered and non-powdered gloves.\(^{(343)}\) The most powerful study investigating the use of non-powdered gloves, which was associated with lower exposure, was a longitudinal case crossover intervention. Substitution of powdered latex gloves with low-protein, powder-free NRL gloves or latex-free gloves greatly reduces NRL aeroallergens, NRL sensitization and NRL asthma in health care workers. None of the individual studies fulfilled strict criteria for good-quality intervention studies, i.e., they were observational studies without a randomized design. However, taken together, these studies support assertions that substitution of NRL greatly reduces NRL sensitization and asthma.

Fewer studies are available for asthma-inducing agents other than NRL. A modest increase in use of control measures and proper work practices has included the use of local exhaust ventilation and decreased use of compressed air. Studies have been undertaken with interventions comprising combinations of different preventive dust control measures, as well as education and PPE, for laboratory animals,\(^{(344, 345)}\) detergent enzymes,\(^{(319, 346)}\) anhydrides,\(^{(347)}\) diisocyanates,\(^{(348)}\) and baking operations.\(^{(93, 349)}\)

Skin exposure to certain occupational asthma inducing agents may increase the risk of occupational asthma, despite the limited epidemiological studies to date primarily regarding diisocyanate exposure. The contribution of skin exposure to asthma risk probably varies greatly with different allergenic exposures, work processes and settings, as well as other factors than can alter skin barrier function. Elimination of exposure, the preferred approach to preventing occupational asthma, reduces all routes of exposure, including skin exposure. Concern that skin exposure to chemical allergens and even possibly to HMW protein allergens may increase asthma risk has arisen based on several lines of “evidence,” including clinical experience and case reports, animal studies, and limited epidemiological findings.\(^{(23, 350, 351)}\) Indirect exposure by others to work areas where asthmagens are in use is also of concern.\(^{(352)}\)

Use of PPE, particularly respirators, is considered less effective than eliminating or minimizing exposures at the source or in the environment.\(^{(353)}\) The success of respiratory personal protection requires an ongoing commitment by employers and employees to the selection, cleaning, maintenance and storage of equipment, as well as training, fit testing, and medical monitoring of users. Respirators are best used as an interim measure while efforts to control exposures at the source or in the environment are being implemented, or when controls at these other levels are not possible. Respirators have often been used in conjunction with other control activities at the source and/or environmental level. Such comprehensive exposure control systems that include the use of respirators have been implemented for workers exposed to laboratory animals,\(^{(345, 354-356)}\) dusts and fumes in aluminum production,\(^{(357)}\) diisocyanates,\(^{(358)}\) and disinfectants.\(^{(7, 359)}\) Although success at prevention has been reported, it is not possible to determine the contribution made by respirators alone.

Statements from professional organizations have addressed use of respirators for primary prevention of work-related asthma. An expert panel convened by the American College of Chest Physicians (ACCP)
produced a publication on the diagnosis and management of work-related asthma. This document advises primary prevention by controlling exposures to known workplace sensitizers and irritants, briefly citing a variety of methods, including respirators. The British Occupational Health Research Foundation (BOHRF) also developed guidelines for occupational asthma. Similar to the ACCP document, the BOHRF guidelines emphasize reducing airborne exposures to occupational asthma agents. The advice specific to respiratory protective equipment (RPE) was: "use of RPE reduces the incidence of, but does not completely prevent, occupational asthma." The European Respiratory Society has recently reviewed the topic and concluded that there is little direct evidence that use of respirators is effective for the primary prevention of occupational asthma. Elimination or minimization of exposures was considered to be more effective.

There are a few studies that directly test whether respirator use is associated with a decline in the onset of occupational asthma. In one study, automobile body shop employees who applied paints containing diisocyanates were approximately one-third as likely to have occupational asthma symptoms if they used a positive pressure respirator. However, a relatively small number of participants used this respirator and the finding was not statistically significant. A second study provided evidence that inconsistent use of respiratory protection might have negative consequences. Specifically, diisocyanate-exposed workers at a wood products plant were at greater risk for new-onset asthma-like symptoms if they removed their respirators even briefly (p = 0.05). A more direct investigation of the value of respiratory protection for primary prevention was conducted among workers who were manufacturing an epoxy resin utilizing hexahydrophthalic anhydride (HHPA). Study participants were offered a choice of three different respirators: a disposable dust and mist respirator, a half-face organic vapor respirator, or a full-face organic vapor respirator. The highest annual incidence for asthma over the 7 years of follow-up was 2%, compared to approximately 10% that was observed in employees before the introduction of respirators. There was no statistically significant difference between respirators, but none of the workers who wore the full-face respirators developed occupational asthma, even those who worked in high-exposure jobs.

MEDICAL SURVEILLANCE

Medical surveillance is the systematic collection and analysis of health data from defined populations for the purpose of prevention and is considered secondary prevention by preventing advanced disease in exposed workers. There are generally three stages in the process: 1) data collection and analysis; 2) preventive interventions; and 3) evaluation. Medical surveillance is not the detailed diagnoses of an individual patient, epidemiologic research, individual case reporting, data collection without prevention benefit, or a substitute for exposure control. It is not hazard surveillance, in which exposure and processes are measured, nor is it biomonitoring, which in the context of occupational asthma, is used to assess exposure to a few specific occupational asthmagens.

While engineering controls are the ideal solution for exposure control and primary prevention, they are often not possible due to technology, lack of substitutions, or cost. If there is any possibility of exposures to occupational asthmagens, a medical surveillance program is appropriate. Additionally, medical surveillance has been found beneficial by identifying work processes associated with incidence of occupational asthma. Multiple surveillance methods for occupational asthma have been utilized, and the methods have varied by setting. The goal is to include all potentially exposed workers in a health surveillance program that can be effective for secondary prevention, the early identification of occupational asthma before permanent impairment occurs. A diagnosis of occupational asthma (i.e., asthma caused by work) should not be made on the basis of history alone, but be supported by physiological and immunological investigations of proven diagnostic benefit. Following a validated diagnosis of occupational asthma, physicians should recommend early avoidance of further exposure, because this offers the best chance of complete recovery. If appropriate and timely interventions are not taken, the prognosis of occupational asthma is poor, with only approximately one-third of workers achieving full symptomatic recovery.
Medical surveillance methods for early detection of occupational asthma in worker groups known to have sensitizer exposure in the workplace most frequently use a health questionnaire, spirometry, peak expiratory flow monitoring and, for specific asthmagens, antibody and skin prick testing, as recommended elsewhere in this guideline. The focus is to detect “possible” cases and then engage in diagnostic confirmation or exclusion by means of definitive clinical testing. The medical surveillance program may primarily be based on questionnaires but should also include lung function tests to document the temporal change in respiratory function and also identify non-symptomatic workers with respiratory changes consistent with a diagnosis of asthma. If there are positive findings, the individual should be referred to a physician having competence in assessment of occupational asthma so that the evaluation may proceed rapidly to confirm a diagnosis of occupational asthma before worker relocation. The process of objective confirmation of a diagnosis of occupational asthma should proceed immediately and rapidly on reasonable suspicion that occupational asthma may have developed.\(^{[51, 362]}\)

Surveillance questionnaire items found to be most useful in identifying subjects with occupational asthma in surveillance programs were job title and duration of work under the same job title, and identification of products causing symptoms in order to define a process or a product responsible for the respiratory symptoms. The nature and timing of symptoms in relation to work, interval between onset of exposure at work and onset of symptoms, and the status of respiratory symptoms on working days as compared with days away from work (including weekends and vacations) is key. Persistence and timing of symptoms should be evaluated, including if they disappear or change.\(^{[62, 363]}\)

Questionnaires that identify symptoms of wheeze and/or shortness of breath which improve on days away from work or on holiday have a high sensitivity, but relatively low specificity for work-related asthma. Questionnaire items that distinguish occupational asthma confirmed by specific inhalation challenge from non-occupational asthma or symptoms not resulting from asthma were sensitive but non-specific and were more useful for high molecular weight agents than low molecular weight agents. Questionnaire alone would have found all individuals referred for further diagnostic evaluation (i.e., no spirometry benefit).\(^{[364, 365]}\) A change in questionnaire responses over time should lead to assessment of the interval between onset of symptoms and current questionnaire and interval between last occupational exposure and current questionnaire. Questionnaires need as much technical attention and skill as PFTs regarding content items, wording, and cultural relevance. They can be delivered on paper, on-line, assisted, interviewer and are subject to interpretation by the examiner, especially when reviewing sequential questionnaires over time.\(^{[366]}\)

Timing of the surveillance should be at least pre-placement, periodic (with the interval defined by consideration of the history of incidence in reported cases) and upon concern post exposure or onset of significant respiratory illness. Beyond a good questionnaire, occupational asthma medical surveillance frequently includes spirometry. Antibody and skin prick testing may be part of the surveillance scheme for specific asthmagens, if the asthmagens meet criteria for use. Review by a well-qualified objective physician, with experience in the evaluation of occupational asthma is important. Questionnaire answers suggestive of occupational asthma, and significant decrement in FEV\(_1\) and FVC beyond that predicted by age indicates that a confirmatory assessment be performed to confirm not only a diagnosis of asthma but also to establish whether temporal changes in pulmonary function correlate with symptoms in the workplace. The confirmatory assessment is essentially to diagnose or exclude the diagnosis of occupational asthma, and recommended methods are as noted in the diagnosis section of this guideline. Serial peak expiratory flow monitoring may be used as part of the initial stages of the confirmatory assessment while the worker is in the workplace to objectively document correlation of loss of airflow with symptoms.\(^{[367-375]}\)

The early detection of cases of occupational asthma should focus primarily on respiratory symptoms and any temporal relationship with work, as opposed to reliance upon spirometry. It requires a coordinated approach between occupational health, primary care and secondary health care. There should be as few steps as possible between symptom detection and final diagnosis to diminish loss of initially identified
cases to follow-up. Use of a two-step screening process, identifying work-related symptoms and presence of sensitization in general or sensitization to work-related high molecular weight allergens, is the most efficient approach to identify potential cases of high molecular weight occupational asthma. For example, a strategy identifying bakers with sensitization to a work-related asthmagen (positive serological test against wheat flour or fungal a-amylase) and also reporting upper respiratory symptoms was the most effective strategy at identifying early stage baker’s asthma, reducing exposures and improving outcomes. In another study of workers exposed to laboratory animal allergens, a two-step prediction rule based on work-related symptom reports, and positive skin prick tests indicating atopy, was able to accurately identify those workers to be subsequently evaluated by skin testing to lab animal allergens.

One-time screening, as in cross-sectional studies, misses cases due to the low prevalence of occupational asthma, healthy worker effect, and selection bias (those affected select out of employment). But routine surveillance may underestimate cases without ongoing participation. Case loss is minimized by longitudinal study and follow-up as long as inception cohort is stable and no workers are lost to follow-up. However, cases detected by one-time screening had less severe asthma than cases from pre-screening era, in cases confirmed by specific inhalation challenge, and had a better outcome at time of diagnosis and 2 years later.

State and federal surveillance programs such as NIOSH Sentinel Event Notification System for Occupational Risks (SENSOR) have limits as most cases are reported “without objective evidence” of asthma such as spirometry, serial peak expiratory or methacholine challenge being impractical, specific inhalation challenge being infeasible or unavailable. State reports of occupational asthma are mainly from health care providers and are affected by practice variability. State reporting requirements are variable, and are often ignored. Voluntary physician reporting is frequently unreliable, unrepresentative, and not effective in prevention.

A decline in the number of workers’ compensation occupational asthma cases due to isocyanates has been noted in Ontario after surveillance for diisocyanates was introduced. Occupational asthma from all causes was diagnosed earlier and indicators of severity of asthma were also milder. Although engineering and industrial hygiene measures may have contributed to these changes, the findings indicated a beneficial contribution from the medical surveillance program for workers exposed to diisocyanates. However, the reduction in the number of cases could not be directly attributed to the performance of medical surveillance alone.

MANAGEMENT OF OCCUPATIONAL ASTHMA (OA)
The medical management of occupational asthma and outcome of interventions following a confirmed diagnosis of OA may depend on several factors, including the worker’s age and the causative agent. Early diagnosis and early avoidance of further exposure, either by relocation of the worker or substitution of the hazard, offer the best chance of complete recovery. Patients with sensitizer-induced OA should be removed from further exposure to the causative agent in addition to providing other asthma management. If medical removal is not possible, exposure should be minimized to as low as possible by means of worker relocation. Relocated workers should have increased health surveillance to demonstrate the absence of worsening of disease.

Determining the most effective treatment for OA requires having precise information on the effect of different management options on clinical, physiological, and socioeconomic outcomes. However, the evidence that can be derived from current data has been limited by methodological weaknesses. There are very few articles that meet the methodologic quality of a randomized controlled trial or prospective cohort study, thus the recommendations regarding management of occupational asthma are made on the basis of consensus due to insufficient evidence.
1. Recommendation: Management of Asthma (Persistence of Exposure)
It is recommended that patients, physicians, and employers be informed that persistence of exposure to the causal agent is likely to result in a deterioration of asthma symptoms and airway obstruction.

    Strength of Evidence – Recommended, Insufficient Evidence (I)
    Level of Confidence – High

2. Recommendation: Management of Asthma (Avoidance of Exposure)
It is recommended that patients and their physicians be aware that complete avoidance of exposure is associated with the highest probability of improvement, but may not lead to a complete recovery from asthma.

    Strength of Evidence – Recommended, Insufficient Evidence (I)
    Level of Confidence – High

3. Recommendation: Management of Sensitizer-induced Asthma (Reduction of Exposure to Low Molecular Weight Asthmagens)
Reduction of exposure is not recommended as a strategy for certain low molecular weight asthmagens (diisocyanates). As an alternative to complete elimination of exposure, continued low level exposure with use of personal protective equipment has been associated with adverse health outcomes and including reports of death.

    Strength of Evidence – Not Recommended, Insufficient Evidence (I)
    Level of Confidence – Moderate

4. Recommendation: Management of Sensitizer-induced Asthma (Reduction of Exposure)
Reducing exposure to the causal agent is NOT RECOMMENDED (I) as a strategy in the management of sensitizer-induced asthma, as available evidence indicates that many asthma cases will worsen in continued exposure. However, it is recognized that some workers will insist on remaining in their jobs for social, economic, and professional reasons, despite counseling on the adverse health consequences. Continued exposure, even at low levels, may result in worsening asthma. If such patients remain in exposure, documentation of the recommendation regarding removal is RECOMMENDED (I). Required close and careful medical monitoring of such patients is RECOMMENDED (I) in order to ensure early identification of worsening asthma. Reducing exposure to the causal agent in addition to providing immunotherapy and other asthma management, where applicable, may be RECOMMENDED (I), and will depend on the asthmagen, level of exposure, severity of asthma (see Table 5), and the clinical judgment of the physician.

    Strength of Evidence – Not Recommended, Insufficient Evidence (I)
    Level of Confidence – Moderate

5. Recommendation: Management of Irritant-induced Asthma (Reduction of Exposure)
For irritant-induced asthma, it is recommended that exposure reduction to the lowest levels possible and careful medical monitoring should be performed to ensure early identification of worsening asthma.

    Strength of Evidence – Recommended, Insufficient Evidence (I)
    Level of Confidence – Moderate

*Workplace exposure is defined as follows:
- Low exposure: when regular airborne exposure to the causative agent is not expected.
- Moderate exposure: when airborne exposures are at or below the level of the occupational exposure limit (OEL) of the causative agent are expected.
- High exposure: when airborne exposures above the level of the occupational exposure limit (OEL) of the causative agent are expected.
- The occupational exposure limit (OEL) selected should be a recent, scientifically reviewed, widely-used guideline designed for use by industrial hygienists in making decisions regarding safe levels of exposure to various chemical substances and physical agents found in the workplace, such as the American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Values (TLVs®).

**Severity is defined as per severity of asthma and asthma control, as defined in the Global Initiative for Asthma Guidelines:**
- Severe OA: having abnormal FEV₁ (<70%) and requiring use of high-dose inhaled corticosteroids and long-acting inhaled beta-agonists for symptom control.
- Moderately Severe OA: having abnormal FEV₁ (<70%) and symptoms that are well-controlled with low dose inhaled corticosteroids and long-acting inhaled beta-agonists.
- Low Severity OA: having normal FEV₁ and symptom control by as needed beta-agonist rescue or with low-intensity controller treatment such as low dose inhaled corticosteroids, leukotriene receptor antagonists or chromones.

   
   The use of respiratory protective devices is not recommended as a safe approach for managing asthma, especially in the long-term and in patients with severe asthma.
   
   *Strength of Evidence – Not Recommended, Insufficient Evidence (I)*
   
   *Level of Confidence – High*

7. **Recommendation: Management of Asthma (Anti-asthma Medications)**

   Anti-asthma medications are not recommended as a reasonable alternative to environmental interventions such as exposure reduction or medical removal.

   *Strength of Evidence – Not Recommended, Insufficient Evidence (I)*
   
   *Level of Confidence – High*

8. **Recommendation: Management of Asthma (Pharmacological Treatment)**

   It is recommended that the pharmacological treatment of work-related asthma follow general recommendations for asthma. The current ATS/ERS recommendations for treatment of severe asthma should be followed.

   *Strength of Evidence – Recommended, Evidence (C)*

   It is recommended that immunotherapy may be considered in settings where occupational asthma due to a specific HMW allergen has been established, when only one or a few allergens have been linked clinically to disease, when there is a standardized commercial allergen extract available for treatment, good control with pharmacotherapy cannot be established and the causative agent cannot be completely avoided for economic, professional or other reasons.

   **Strength of Evidence – Recommended, Insufficient Evidence (I)**

   **Level of Confidence – Moderate**

**MANAGEMENT OF IRRITANT-INDUCED OA**

After acute inhalation of a respiratory irritant, acute airway responses should be assessed early and may require supplemental oxygen, bronchodilators, and corticosteroids. Although there is little objective evidence for the effectiveness for systemic corticosteroid therapy, this is often used for treatment in the hope of limiting airway inflammation. In individuals with subsequent irritant-induced asthma or WEA, optimizing asthma treatment and reducing the exposure to relevant workplace triggers has been recommended. If not successful, change to a workplace with fewer triggers is suggested in order to control asthma. Limited data exist on the effect of the cessation of exposure in patients with irritant-induced OA. One report of three patients with repetitive exposure to irritants at work suggested a benefit for removal from the exposure. Improvement in symptoms, though not always NSBHR was found in aluminum potroom workers after cessation of exposure. Unlike workers with sensitizer-induced OA, workers with irritant-induced OA may be able to continue in their usual jobs if the risk of a similar high-level exposure to the inciting irritant substance is diminished via engineering controls and similar means are employed to prevent subsequent WEA, including the appropriate use of respiratory protective devices. The rationale for this approach is based on the unproven assumption that irritant-induced airway inflammation in patients with irritant-induced OA will diminish with a reduction of exposure that is analogous to what may occur in patients with occupational or tobacco smoke-related chronic bronchitis with a reduction in exposure.

**MANAGEMENT OF WEA**

The literature on the natural history and management of patients with WEA is limited, and the factors that predict outcome are not well defined. The few studies completed to date have significant methodologic weaknesses and evaluated different treatment or preventive strategies in WEA patients. The goal of treatment is to minimize asthma exacerbations by reducing work exposures (e.g., by limiting sources of exposure, improving ventilation) and optimizing standard medical management with nonwork environmental control measures and pharmacologic treatment. The patient may be able to stay at the same job with reduced exposures, depending on the severity of asthma and extent of exacerbating factors at work, but a job change to a workplace with fewer triggers may be necessary if this approach fails to adequately prevent work-related exacerbation of symptoms. When a WEA case can no longer tolerate a work setting, the clinician and patient should carefully balance the potential benefit of removal from work with the benefits (financial and psychological) of continued working. Workers with work-exacerbated asthma had reduced airway inflammation and improved quality of life after the implementation of smoke-free environment legislation.

**MANAGEMENT OF SENSITIZER-INDUCED OA**

Following the diagnosis of sensitizer-induced OA, management decisions can be complex. For example, while complete avoidance of the sensitizer may be advisable, alternative employment is often not available or feasible, symptoms may initially be mild, and therapy may alleviate symptoms sufficiently to
consider continued employment. This section summarizes the evidence available for the management of sensitiser-induced OA.

PHARMACOLOGIC TREATMENT OF WRA

The pharmacologic treatment of OA and WEA does not differ from the treatment of asthma that is not work related.\(^7\) It relies on a stepwise approach according to the severity of asthma and asthma control, as defined in the Global Initiative for Asthma Guidelines\(^{389, 396}\). Treatment for patients with a diagnosis of severe asthma has been recommended by the ATS/ERS but the recommendations did not exclude nor specifically address OA or WEA.\(^{397}\) The physician and the patient should discuss and create a written “asthma action plan.” Pharmacological management of patients with asthma should occur in conjunction with recommendations to avoid exposure to the causative agent.\(^{61, 362}\) However, there is currently insufficient evidence that treatment with inhaled corticosteroids and long-acting β2-agonists is able to prevent the long-term deterioration of asthma in subjects who remain exposed to the agent causing occupational asthma.\(^{388}\) The methodological quality of the studies is low, the sample sizes are small, and dissimilar populations and interventions have precluded meta-analytic synthesis.\(^7\)

There are very few studies that have specifically examined pharmacologic treatment in the management of OA. The effectiveness of anti-asthma medications in patients who remain exposed to the causal agent has not been specifically addressed in some of the previously published guidelines\(^7, 51\) or in the Agency for Healthcare Research and Quality (AHRQ) systematic review.\(^1\) The AHRQ review identified 10 controlled clinical trials specifically involving patients with sensitiser-induced OA, of which several were short-term trials examining acute effects on the response to SIC. There was no significant deterioration in any of the asthma outcomes compared with baseline values in 10 subjects with occupational asthma due to various agents who were treated with inhaled corticosteroids and long-acting β2-agonists over a 3-year period.\(^{398}\) In contrast, another study reported that the decline in FEV\(_1\) before removal from exposure to agents causing occupational asthma was not affected by the use of inhaled corticosteroids.\(^{399}\) A pilot study used treatment with leukotriene inhibitors.\(^400\)

Proposed Occupational/Work-Related Asthma Guideline
MTUS – 8 C.C.R. § 9792.23.10 (Public Forum – October 2015)
Inhaled Corticosteroids

It may be beneficial to initiate an early treatment with inhaled corticosteroids in subjects with sensitizer-induced OA in addition to removal from exposure, although there is insufficient evidence to support systematic treatment with high-dose inhaled corticosteroids. The AHRQ systematic review noted that after treatment with steroids, most of the available studies documented an improvement in asthma.
symptoms and NSBHR, and an increase in mean FEV₁, although only a few reported complete resolution of symptoms in the majority of the subjects. Two randomized controlled trials assessed the effects of systematic treatment with inhaled corticosteroids in addition to cessation of exposure. Treatment with beclomethasone dipropionate (1 mg twice daily for 5 months) was associated with reduced NSBHR.⁴⁰³ Beclomethasone dipropionate (1 mg daily) was associated with a significant, though minimal, improvement in symptoms, peak expiratory flow and quality of life but no change in specific responsiveness to the causative agent (diisocyanates).⁴⁰⁴

Evidence for the Use of Inhaled Corticosteroids
There is 1 high-⁴⁰⁴ and 2 moderate-quality RCTs/crossover studies incorporated into this analysis.⁴⁰³,⁴⁰⁵ There are 2 other studies⁴⁰⁶ in Appendix 1.

MANAGEMENT OF SENSITIZER-INDUCED OA BY IMMUNOTHERAPY
Immunotherapy is a possible treatment option for patients with sensitizer-induced OA, but there is limited evidence to support its efficacy except under selected circumstances. Immunotherapy could be considered in settings where OA due to a specific HMW allergen has been established, when only one or a few allergens have been linked clinically to disease, when there is a standardized commercial allergen extract available for treatment, good control with pharmacotherapy cannot be established and the causative agent cannot be completely avoided for economic, professional or other reasons. There is a lack of evidence-based information on the effectiveness and adverse effects of specific immunotherapy with high molecular weight occupational allergens. Immunoone therapy for high molecular weight antigens should be most effective when it targets one allergen or a few allergens in the workplace that are linked clinically to disease, and it may have less effect when the worker is also sensitized to environmental allergens not included in the extract. Immunotherapy for OA due to LMW chemicals is untested because of concerns about toxicity and the unclear role of IgE-associated sensitization. Immunotherapy may be given by the standard subcutaneous route, where there is ample published literature for some non-occupational allergens, or by the sublingual route, for which there is less information about efficacy especially with occupational allergens. Systemic reactions to immunotherapy are less frequent with the sublingual approach.

There have been a limited number of studies of immunotherapy with HMW allergens of potential occupational relevance. These include natural rubber latex (NRL) for health care workers, venom from stinging insects for beekeepers, wheat for bakers, and grass or ragweed pollen for outdoor workers. Subcutaneous immunotherapy for exposure to NRL has been shown to be effective in reducing workplace symptoms, specific skin reactivity, and medication use, but has not yet been shown to improve the clinical course of OA. These studies documented an improvement in rhinoconjunctivitis symptoms and a reduction in skin reactivity to latex, but there was no clear improvement in asthma outcomes. In addition, latex immunotherapy resulted in frequent systemic adverse reactions. Sublingual NRL immunotherapy has similar effects, but anaphylaxis occurred with higher doses.

Specific occupations have characteristic challenges that may affect management. Hymenoptera venom allergy is an occupational hazard of beekeepers and other outdoor workers. Immunotherapy is highly effective and is indicated for those with sensitizer-induced OA associated with severe anaphylaxis who are at risk for future stings. A placebo-controlled, double-blind trial of subcutaneous immunotherapy with a flour extract in 30 bakers with occupational asthma demonstrated that the treated patients showed a significant decrease in subjective symptoms, NSBHR to methacholine, and skin sensitivity and specific immunoglobulin (IgE) to wheat flour without any adverse reactions. A later study demonstrated diminished symptoms and drug use in a cohort of bakers after similar treatment. No studies have evaluated the efficacy of immunotherapy for laboratory animal allergy in animal workers (e.g., researchers and veterinarians), compared to the many studies for pet allergy. In non-occupational environmental settings, immunotherapy has been shown to prevent progression from rhinitis to asthma, and thus has the potential ability to alter the natural history of the disease. Immunotherapy is not indicated to treat irritant-induced asthma.

Evidence for the Use of Immunotherapy
There are 2 moderate-quality studies incorporated into this analysis. There is 1 low-quality and 6 other studies in Appendix 1.

MEDICAL REMOVAL

Once a diagnosis of OA is confirmed, the patient should be advised (preferably verbally and in writing) that the prognosis is improved by early and complete removal from exposure. Symptoms and functional impairment associated with OA may persist for many years after avoidance of further exposure to the causative agent. Persistence of exposure to the agent causing occupational asthma is more likely to be associated with the persistence of asthma and NSBHR, and an accelerated decline in FEV₁, compared with complete avoidance of exposure. The systematic review conducted by the AHRQ concluded that workers with occupational asthma who remain exposed to the causal agent continue to experience stable or worsened asthma symptoms and tend to show a decrease in FEV₁ over time, as well as an increase in NSBHR. The consequences of persistent exposure were not specifically examined in the clinical practice guidelines issued by the British Occupational Health Research Foundation (BOHRF) and the American College of Chest Physicians (ACCP).

Exposure Control as Treatment

As stated in a recent Cochrane review regarding workplace interventions for the treatment of OA, “There is very low-quality evidence that removal from exposure improves asthma symptoms and lung function compared with continued exposure. Reducing exposure also improves symptoms, but seems not as effective as complete removal. However, removal from exposure is associated with an increased risk of unemployment, whereas reduction of exposure is not. The clinical benefit of removal from exposure or exposure reduction should be balanced against the increased risk of unemployment.” However, there is some case report and small cohort study literature that supports removal or reduction of exposure to the causative agent. Exposure reduction and/or removal has been recommended by others, including BOHRF, ACCP, and the European Respiratory Society (ERS).

The likelihood of improvement or resolution of symptoms or of preventing deterioration is greater in workers who have no further exposure to the causative agent. The consequences of persistent exposure to the causal agent are more frequent persistence of symptoms and decline in pulmonary function. Asthma symptoms persist in almost all patients who remain exposed, while one-third of those who avoided exposure recover from their asthma. Persistence of exposure was associated with a decrease in forced expiratory volume in 1 sec (FEV₁) and an increase in NSBHR compared with cessation of exposure. Changes in FEV₁ have been investigated according to cessation or persistence of exposure to the sensitizing agent. Patients with occupational asthma caused by red cedar dust who continued to be exposed had a more rapid decline in FEV₁ than those who were removed. The rate of decline in FEV₁ before and after removal from exposure in individuals with occupational asthma (87% of the cohort due to LMW agents) was significantly greater before than after cessation of exposure. The rate of decline after removal from exposure is similar to that observed in healthy adults.

Redeployment to a low-exposure area is not always effective. Reduction of exposure to the causal agent can lead to improvement or resolution of symptoms and NSBHR, although the limited available evidence indicates that this approach is less beneficial than cessation of exposure. The AHRQ systematic review analyzed the outcome of symptoms, asthma medications, FEV₁, and NSBHR after the reduction of exposure in studies published up to 2004. The review concluded that the data documented some improvement in asthma symptoms; no clear pattern of changes in medication use; an improvement in FEV₁ over time in less than half of the studies; and provided insufficient data (improvement in one of three studies) to draw conclusions about the changes in NSBHR. The guidelines of the BOHRF and ACCP stated that reduction of exposure “is not always effective” and that “there is little evidence for using this approach.” If workers are redeployed, exposure should be minimized to as low as possible by means of worker relocation. Relocated workers should have increased health surveillance to demonstrate the absence of worsening of disease.
The likelihood of improvement or resolution of symptoms or of preventing deterioration is greater in workers who have shorter duration of symptoms prior to avoidance of exposure. A meta-analysis regarding asthma outcomes (i.e., improvement, recovery, and worsening of asthma symptoms and NSBHR) compared subjects who reduced exposure to the causal agent with those who completely avoided exposure. The most commonly identified causal agents, in seven out of 10 publications, were LMW agents, including isocyanates, colophony, red cedar dust, platinum salts, and persulfate salts. Two studies involved a single HMW agent, NRL, and one study evaluated patients with occupational asthma caused by various agents, of which 90% were LMW agents. The meta-analysis of pooled data showed that a reduction of exposure was associated with a lower likelihood of improvement and recovery of asthma symptoms and a higher risk of worsening of the symptoms and NSBHR compared with complete avoidance of exposure.

Patients should be informed of the possible adverse health effects of continuing exposure to themselves and to co-workers should they not permit necessary workplace investigations. Communicating with the workplace is useful, but requires the patient’s written consent. Employers and their health and safety personnel should ensure that measures are taken to ensure that workers diagnosed as having occupational asthma avoid further exposure to its cause in the workplace.

Respiratory personal protective equipment (RPPE) can result in an improvement – but not complete elimination – of respiratory symptoms and airway obstruction in the short term. Studies investigating the effectiveness of RPPE in those with OA are limited to small studies in provocation chambers or limited case reports. Air-fed helmet respirators may improve or prevent symptoms in some but not all workers who continue to be exposed to the causative agent. Use of RPPE led to a significant reduction in respiratory symptoms and changes in functional parameters during short-term exposures, but failed to provide complete protection. There was no protective effect in workers with more severe asthma or in those who used RPPE irregularly. The proportion of workers with occupational asthma induced by red cedar dust who used a twin-cartridge respirator and remained exposed to the causal agent was significantly higher among the group with stable asthma than among the group with a deterioration of asthma. None of these studies provide information on practical issues (e.g., compliance) that could result from the long-term use of RPPE. Individuals with asthma might have difficulty adapting to a dual cartridge half-face mask respirator due to increased inspiratory resistance resulting in increased respiratory cycle time.

An exception is isocyanate-induced OA. This requires removal from exposure, as there have been reported deaths in patients on medication and using respiratory protection. Studies have found that “continued TDI exposure has been associated with increasingly persistent and severe respiratory symptoms.” Several early investigators described a progression of symptoms with decreasing exposure-response intervals and increasing severity of bronchospasm. In addition, a significant decline in FEV₁ was observed among subjects with TDI-induced asthma who remained on the job (average duration 27 months), whereas a modest improvement in FEV₁ was observed among those who left. Similar results were reported in another study. There have been several cases of fatal bronchospasm reported in persons diagnosed with or believed to have had TDI-induced asthma at the time of an exposure incident. The earlier case report pertained to an automobile refinisher with TDI-induced asthma, who continued working with a two-component PUR paint and subsequently died during a severe asthma attack 6 years later. This person had used a bronchodilator and steroids for asthma control and reported using a respirator to reduce exposure.

Evidence for Removal/Reduction of Exposures
There are 11 other studies incorporated into this analysis. None of these studies met the criteria for high- or moderate-quality studies, but are incorporated into this section (not Appendix 1) for the reader’s ease of review.

OUTCOME

Prognosis of OA

The long-term consequences of OA are variable and require prolonged follow-up. Symptoms and functional impairment associated with OA may persist for many years after avoidance of further exposure to the causative agent. Outcomes are best in those patients with a shorter duration of exposure after onset of symptoms.\(^7\) Evidence supports the view that OA may become a chronic condition, similar to non-OA, and may require similar prolonged medical management.\(^{51, 387}\)

The symptoms and functional impairment of OA caused by various agents may persist for many years after avoidance of further exposure to the causative agent.\(^{128, 175, 250, 276, 358, 392, 426, 434, 436, 440, 447, 451, 466, 471-479}\) Improvement or resolution of symptoms or of preventing deterioration is more likely in workers who have:

1) no further exposure to the causative agent,\(^{128, 246, 247, 358, 426-429, 431-433}\)

2) relatively normal lung function at the time of diagnosis,\(^{128, 426, 436, 447, 448, 479, 480}\) and

3) shorter duration of symptoms prior to diagnosis.\(^{128, 358, 426, 429, 430, 446, 448, 449, 479}\)

The AHRQ review of sensitizer-induced OA demonstrated continued improvement of lung function, often requiring follow-up durations of more than 2 years.\(^1\) Prolonged follow-up has also been required to demonstrate improvement in nonspecific airway responsiveness. However, complete avoidance of exposure to the causal agent results in symptom recovery and resolution of NSBHR in less than one-third of affected workers.\(^{388}\) A systematic review of the outcome of sensitizer-induced OA reported a pooled estimate of symptomatic recovery of 32%, within a median duration of follow-up of 31 months. The pooled prevalence of persisting nonspecific bronchial hyperresponsiveness was 73% and was significantly greater for those with OA from HMW agents compared with those with OA from LMW agents.\(^{481}\) More recent studies published subsequently to the review by Rachiotis yielded similar estimated rates of symptomatic recovery and persistence of NSBHR.\(^{106, 165, 167, 168, 482, 483}\)

Improvement in NSBHR can continue for years after cessation of exposure, but the rate of improvement is steeper during the first 2.5 years.\(^{484}\) A determinant of improvement in NSBHR at follow-up has been found to be the severity of NSBHR at diagnosis.\(^{439}\) Induced sputum analysis has demonstrated that failure to improve NSBHR after cessation of exposure was associated with persistent airway inflammation.\(^{480, 485}\) but inflammation and airway remodelling may be present in subjects who have recovered from symptoms and NSBHR.\(^{106, 486}\) The long-term outcomes of acute irritant-induced asthma are thought to be no different.\(^{487}\) However, a cohort study of pulp mill workers found that irritant peak exposure during gassing episodes was a strong predictor of changing work due to respiratory problems, even after adjustment for asthma, chronic bronchitis, and chronic rhinitis.\(^{488}\)

OA may become a chronic condition, similar to non-OA, and may require similar prolonged medical management. Patients with confirmed or possible OA should be followed up at a specialist center while risks of continuing exposure to allergen remain. The recommended follow-up is every 3 months for 1 year, and then every 6 months thereafter. Patients with confirmed OA who have left work, or who have no ongoing asthmagen exposure risk, should be followed up for a minimum of 3 years at a specialist center.\(^{51, 387}\) Patients with a diagnosis of OA should be followed with pulmonary function testing and nonspecific airway responsiveness testing (if available), unless asthma has cleared, regardless of their continued exposure status.\(^7\)

Employment Outcome

The risk of unemployment may\(^{469}\) or may not,\(^{490, 491}\) be higher than in other adult asthmatics and may fall with increasing time from diagnosis.\(^{446}\) Approximately one-third of workers with OA are unemployed up to six years after diagnosis.\(^{118, 440, 446, 478, 489-493}\) Workers with OA suffer financially.\(^{23, 118, 440, 489, 491, 492}\) Systems that incorporate retraining may be more effective than those that do not.\(^{492, 494}\)
One prospective study compared asthma severity, disease-related costs and work-derived income after cessation or persistence of exposure to various agents causing occupational asthma. Noticeably, the investigators did not clearly distinguish the persistence of exposure to the same conditions at work from a reduction of exposure to the causal agent, since 43% of the subjects with persistent exposure actually had intermittent or lower exposure. When compared with persistence of exposure to causal agents, complete avoidance resulted in a significant decrease in asthma severity and health care expenses, but also in work-derived income. Two publications reported on the socioeconomic outcomes of workers with occupational asthma caused by colophony and NRL gloves. These studies revealed that the rate of unemployment was significantly higher among those who avoided exposure compared with those who reduced exposure. Among workers with latex-induced occupational asthma, a “major” loss of income was more frequently reported by subjects who ceased exposure to latex than by those who remained exposed to reduced levels of latex. A recent case review found that continued employment in the same job 6 months after diagnosis of OA could not be predicted by FEV₁, gender, age, occupational status, exposure antigen, smoking habits, or duration of symptoms before diagnosis; only atopy was a prognostic factor.

Pulmonary rehabilitation may be effective even in the complex settings of occupational respiratory diseases, including asthma, providing sustained improvement of functional capacity, and reducing health care utilization. No studies have made direct comparisons between different systems of rehabilitation.

Specialty Care (When do you refer to a pulmonary or allergy specialist?)
The National Heart, Lung, and Blood Institute (NHLBI) has established the following guidelines for referral of adult patients to a medical specialist in asthma:

- Patient has had a life-threatening asthma exacerbation.
- Patient is not meeting the goals of asthma therapy after 3-6 months of treatment. An earlier referral or consultation is appropriate if the physician concludes that the patient is unresponsive to therapy.
- Signs and symptoms are atypical suggesting an alternative diagnosis.
- Other conditions complicate asthma or its diagnosis (e.g., sinusitis, nasal polyps, aspergillosis, severe rhinitis, vocal cord dysfunction, gastroesophageal reflux disease, and COPD).
- Additional diagnostic testing is indicated (e.g., allergy skin testing, rhinoscopy, complete pulmonary function studies, provocative challenge, bronchoscopy).
- Patient requires additional education and guidance on complications of therapy, problems with adherence, or allergen avoidance.
- Patient is being considered for immunotherapy.
- Patients that require more intense therapy in the stepwise algorithm for the management of asthma as per the NHLBI guidelines (NHLBI: Step 4 care or higher or step 3 for children 0-4 years of age. Consider referral if patient requires step 3 care or step 2 for children 0-4 years of age.)
- Patient has required more than two bursts of oral corticosteroids in 1 year or has an exacerbation requiring hospitalization.
- Patient requires confirmation of a history that suggests that an occupational or environmental inhalant or ingested substance is provoking or contributing to asthma.
- Depending on the complexities of diagnosis, treatment, or the intervention required in the work environment, it may be appropriate in some cases for the specialist to manage the patient over a period of time or to co-manage with the primary care physician.
- In addition, patients who have significant psychiatric, psychosocial, or family problems that interfere with their asthma therapy may need referral to an appropriate mental health professional.
for counseling or treatment. These problems have been shown to interfere with a patient’s ability to adhere to treatment.

In general, cases of reversible airways obstruction suspected of work-related asthma should be referred to a specialist in occupational medicine in the following situations:

- The triggering condition or antigen is unknown and the patient continues to work in the environment.
- The worker is planning a return to work or change in jobs or assignment and requires counseling on future risk, accommodation, and fitness for duty.
- The pulmonary specialist in the case is unfamiliar with occupational exposures and the workplace.
APPENDIX 1: LOW-QUALITY/SUPPLEMENTARY STUDIES

The following low-quality/supplementary studies were reviewed by the Evidence-based Practice Asthma Panel to be all inclusive, but were not relied upon for purpose of developing this document’s guidance because they were not of high quality due to one or more errors (e.g., lack of defined methodology, incomplete database searches, selective use of the studies and inadequate or incorrect interpretation of the studies’ results, etc.), which may render the conclusions invalid. ACOEM’s Methodology requires that only moderate- to high-quality literature be used in making recommendations.(497)

Histamine

- Specific lung conductance, dose-response curves for PC20, threshold concentration, reactivity
- Differences in dose response were normally distributed in Yan and Mortagy
- In a smaller group of subjects PC20-FEV1 appeared to be more specific than indices using sGL and maximum partial expiratory flow rates in distinguishing normal from asthmatic responses.
- Thus, of the three methods tested, the Yan technique was the simplest. It is fast, convenient.

<td>N = 4 all with anaphylaxis reaction to exposure to latex</td>
<td>All 4 patients received SIT with aqueous extract. A challenge test was performed in 3/4 patients. Two had no reaction to latex gloves, one had rhinoconjunctivitis.</td>
<td>&quot;We consider SIT with latex to be highly effective, safe and well tolerated provided we use this dose of the allergenic extract.&quot;</td>
</tr>
<tr>
<td>Stern</td>
<td>2000</td>
<td>Case series</td>
<td>NA</td>
<td>N = 2 with systemic reactions to sting (no asthma patients)</td>
<td>Both received SIT. Improvement with systemic symptoms in both cases</td>
<td>&quot;...immunotherapy with BBV is the only safe therapeutic alternative in bumblebee-allergic patients who cannot avoid exposure.&quot;</td>
</tr>
<tr>
<td>Grembiale</td>
<td>2000</td>
<td>RCT</td>
<td>No mention of industry sponsorship or COI</td>
<td>N = 44 subjects with history of atopic rhinitis; mean age 19. All had positive skin prick tests for house dust mite, but negative tests for other common aeroallergens.</td>
<td>Specific Immunotherapy (SIT) group (n = 22) received house dust mite allergen extract conjugated with sodium alginate vs. placebo group (n = 22) received 10 mg/ml of histamine phosphate in physiologic saline. Both groups made monthly visits for 2 years.</td>
<td>Methacholine PD_{20} FEV₁ increased 2.88-fold (p &lt; 0.001) at 1 year of SIT treatment and 4.1-fold (p &lt;0.001) after 2 years compared to pre-treatment values. No difference was found in the placebo group (p = 0.708).</td>
